During the study period, 404 patients were registered and 402 patients were evaluable; the two unevaluable patients underwent vaginal operation. Randomization allotted 201 patients into a continuous and 201 patients into an interrupted fascial closure. One hundred forty-eight patients (36.8%) had a transverse incision and 254 had a vertical incision. Review of the identifying data indicated that the patients could be delineated into two groups: those with a transverse incision and those with a vertical incision (Table II). The two incision groups differed in number of patients, mean age (t test; $p < 0.0001$), weight ($p = 0.0036$), and risk score ($p < 0.0001$). However, within incision type, there was no difference in these factors between those patients with a continuous and interrupted closure. These incision type differences also existed in the postoperative diagnosis (Table III) and the operative procedure (Table IV). As expected, the majority of procedures for surgical treatment of a suspected gynecologic cancer or known malignancy were performed through a vertical incision.

The majority of procedures were classified as clean or clean contaminated (Table V). Mean fascial closure time was statistically ($p < 0.01$) and clinically shorter in the continuous closure group regardless of incision type (Table VI).

Acute and long-term complications were rarely encountered in those patients with a transverse incision (Table VII). Although the overall incidence appeared increased in patients with vertical incisions, there was no statistical or clinical difference in the incidence of seroma or infection ($p = 0.10$). When the continuous and interrupted closures in this series were compared, the risk of hernia was not increased in the presence of infection, and the method of closure did not increase the risk ($p = 0.5$). The mean age and weight for those patients in whom a hernia developed was 59.6 years and 155 pounds. The mean risk score for those with hernias was 2.8 (continuous) and 3.0 (interrupted). Neither complete wound dehiscence nor evisceration developed in any patient.

The infection/seroma rate (2.68) was 2.1% in clean wounds; 3.1% (10/325) in clean contaminated wounds, and 22.1% (2/9) in contaminated wounds.

Comment

A predictable pattern of healing occurs after a surgical incision.[2] Surgical and natural hemostasis, an immediate requirement, is followed by the release of vasoactive substances, an influx of polymorphonuclear leukocytes, and a state of acute inflammation. After 3 days capillary proliferation begins at the wound edge and randomly oriented collagen monomers are found. Approximately 4 days later the phase of collagen maturation begins and the resultant wound stress and covalent collagen binding begins to impart strength to the wound. Even at this time (approximately 7 days), incisional strength remains totally related to suture strength.

Although the wound-breaking tension of a given incision may vary dramatically (with a fivefold to tenfold interpersonal difference), the abdominal fascia apparently regains its strength slowly. In fact, less than 40% of the unwounded tensile strength is present at 8 weeks.[3] The majority of known absorbable sutures actually retain only about 10% of their original tensile strength at 3 weeks[2] and potentially place the abdominal wound at risk for late complications such as hernia formation. Permanent sutures maintain constant tensile strength during this healing period. However, the use of a permanent suture increases the risk of late wound pain or sinus formation. In consideration of these facts, an absorbable suture with a slower loss of tensile strength could be of potential benefit by maintaining wound strength during the early phase of healing and not becoming a permanent foreign body with its inherent problems.

Fascial strength is also related to suture placement.

Tera and Aberg[4] reported that wound closure strength can be doubled in vertical incisions if sutures are placed 1.5 to 2.0 cm away from the linea alba. These data have some clinical support because retrospective clinical studies indicate a low risk of fascial dehiscence in vertical incisions closed with an en bloc technique.[5] Unfortunately, the same clinical data are not available in the closure of transverse incisions because intermediate (7-day) and long-term (21-day) wound strength is not apparently increased with an en bloc closure.[6] Although the transverse incision is only half as strong as a vertical incision closed en bloc,[7] the postoperative stress placed on a transverse incision appears less, and clinically this cosmetic incision performs well. In fact, the clinical success of the transverse incision may not be related to its strength but rather to the bias of physicians to use this incision in young, healthy women.

Knot tying techniques may be as important in maintenance of incisional strength as suture placement. Tight knots potentially strangulate tissue and interfere with optimal wound healing.[6]

The study protocol was designed to control these variables and to evaluate the effects of different methods of wound closure with a single-suture material only.

Few prior reports recognize and control for these potential confounding variables. As a result, gynecologists are required to place over 40 million fascial sutures each year, relying on general surgical data to make decisions. Unfortunately, these data are often biased by the inclusion of males and a different incision placement, both of which may alter the risk of wound outcome.[8]

Not uncommonly, previous prospective papers evaluated different suture composition, different suture size, and different closure techniques in a single protocol.[9, 10] The inclusion of these additional variables even in large studies makes it difficult to clarify the salient information. Wissing et al.[10] recently reported a prospective randomized multicenter study of fascial closure in 1400 patients that evaluated No. 2 polygalactin (interrupted), No. 1 polygalactin (continuous), No. 1 polydioxanone sulfate (continuous), and No. 1 nylon (continuous) sutures.[11] The study was conducted in multiple institutions, there was no stratification of wound risk factors, and there was no report of control of the preoperative or intraoperative factors important in wound healing. However, it apeared that the hernia rate (10.4% to 20.6%) of all reported closure techniques in this prospective study was significantly higher than reported in previous retrospective reviews. In fact, this prospective incidence was twentyfold higher than two recent retrospective reports in the gynecologic literature.[11, 12] In addition, chronic wound pain or wound sinus problems were common with use of permanent suture.[10]

In contrast to previous investigations, our protocol attempted to control for factors that predispose to wound infection since all incisions were closed by experienced gynecologists, patients had a short hospitalization, hair clipping, and short-term antibiotic prophylaxis. Although not usually stated in previous reports, even the last factor may be important because recent data suggest that longer-term prophylaxis may adversely affect wound healing and result in late wound failures.[13] Small (2-0) polyglycolic acid sutures were used during the pelvic portion of the operation. Use of subcutaneous sutures, which potentially increase the risk of infection, and subcutaneous drains were avoided. Each incision was closed with widely placed sutures to approach an optimal suture length to wound length ratio of 4:1.

Our protocol evaluated a polyglyconate suture [32% trimethylene carbonate (pliability) and 68.1% polyglycolic acid copolymer (strength)] that maintains as much as 40% of its tensile strength at 6 weeks.[14] The hydrolysis-associated breakdown allows more gradual

loss of suture strength and theoretically mirrors the return of strength of the healing fascia. The monofilament character of this suture allows ease of passage through tissue and may decrease the risk of infection when compared with braided materials. Surgeon's knots were used because they impart the greatest strength to a suture. Finally, some preoperative attempt to stratify for risk of poor wound outcome was used. Although the risk categorization may at first appear arbitrary, the authors desired that no single risk factor would eliminate a patient from the protocol. Although it might appear that these patients were "low" risk, the mean risk scores suggest that those patients with vertical incisions had a significant incidence of factors that might adversely affect wound outcome.

Our data suggest that wound infection or seroma risks were not affected by the method of fascial closure with use of a strict wound management protocol and a monofilament suture. However, it was interesting that late postoperative seromas (>10 days) developed in 16 patients during the protocol. The risk of incisional hernia was not affected by the method of closure.

The results of our study suggest that in a private practice of gynecology, wound closure by a continuous closure technique with a long-acting absorbable suture appears to be associated with few short-term and long-term wound problems when compared with an en bloc closure. This closure may be performed in less than half the operative time and apparently does not increase the risk of long-term wound complications. The importance of shortening the operative procedure has numerous benefits, both in cost savings and decreasing infectious risks, particularly in those procedures of intermediate operating time when closure may account for as much as 20% of the operative time.

Endometrioma of the liver

Vittorio Rovati, MD,[a] Edoardo Faleschini, MD,[a] Paolo Vercellini, MD,[b] Giovanni Nervetti, MD,[a] Giorgio Tagliabue, MD,[a] and Guido Benzi, MD[b]

Milan, Italy

Hepatic endometriosis is extremely rare. We describe a patient sent to us with epigastric pain as the only symptom and who was found to have associated endometrioma of the liver and left ovary. We suggest a gynecologic evaluation before surgery for hepatic cyst of unknown cause. (Am J Obstet Gynecol 1990;163:1490-2.)

Key words: Endometriosis, liver cyst, abdominal pain

The occurrence of extrapelvic endometriosis is not uncommon. The only organ in the abdominal cavity that is apparently refractory to the disease is the spleen.[1] We are aware of only one case of hepatic endometriosis reported in the literature.[2] We describe another patient with a hepatic endometrioma.

Case report

A 37-year-old nulligravid woman who had never undergone laparotomy was referred to us because of chronic, acyclic epigastric pain of a year's duration not accompanied by other symptoms. At abdominal palpation an epigastric mass was identified of hard elastic consistency and smooth surface, moderately tender, and of probable hepatic origin. Results of the abdominal examination were otherwise normal. Liver ultrasonography showed a septate cystic formation of 10 cm in the left lobe, with low-level echoes. An abdominal computed tomography scan revealed a multilocular cyst of 10 cm diameter with fine calcifications in the wall (Fig. 1). Laboratory values were normal; hepatitis B surface antigen and antibodies were negative. A tentative diagnosis was made of *Echinococcus* cyst containing daughter cyst, and surgical exploration was programmed.

At laparotomy with double subcostal incision extended to the xiphoid process, the left liver lobe had a hard elastic mass on the parenchymal surface, connected to the diaphragm by adhesions. Intraoperative ultrasonography after section of the adhesions and the falciform ligament showed that only the second and third hepatic subsegments were involved. A left lateral

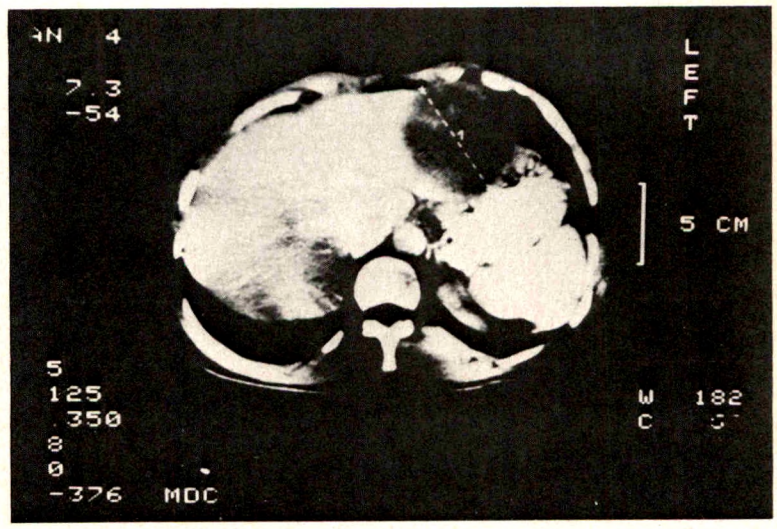

Fig. 1. Computed tomographic scan shows hypodense formation, delimited by wall of greater density containing fine calcifications, located at level of second and third hepatic subsegments.

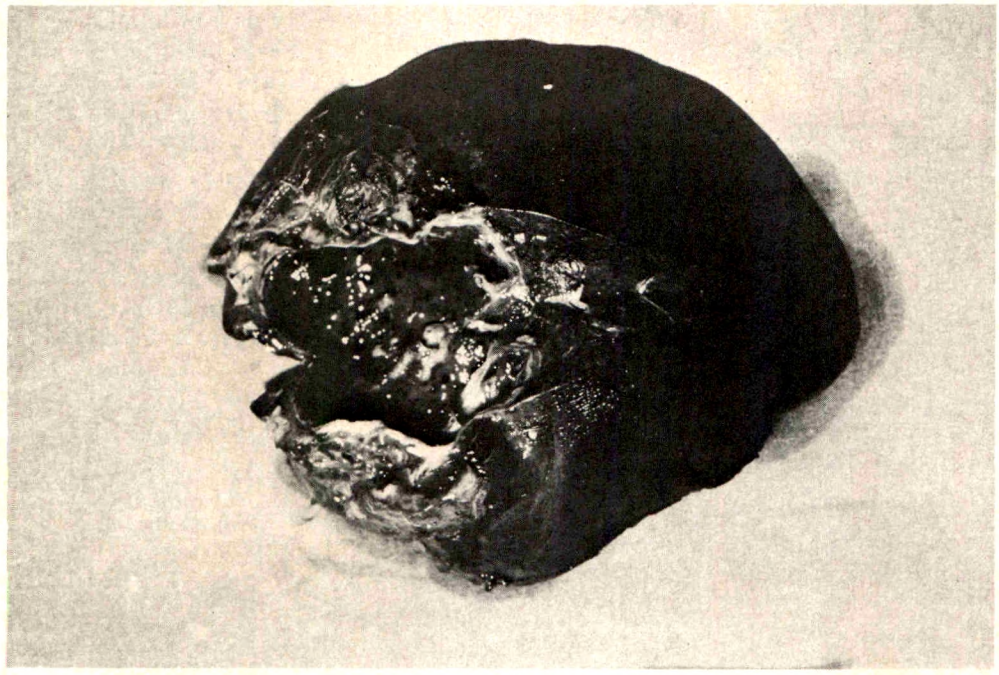

Fig. 2. Left liver segment opened to show endometriotic cyst with typical chocolate-colored material.

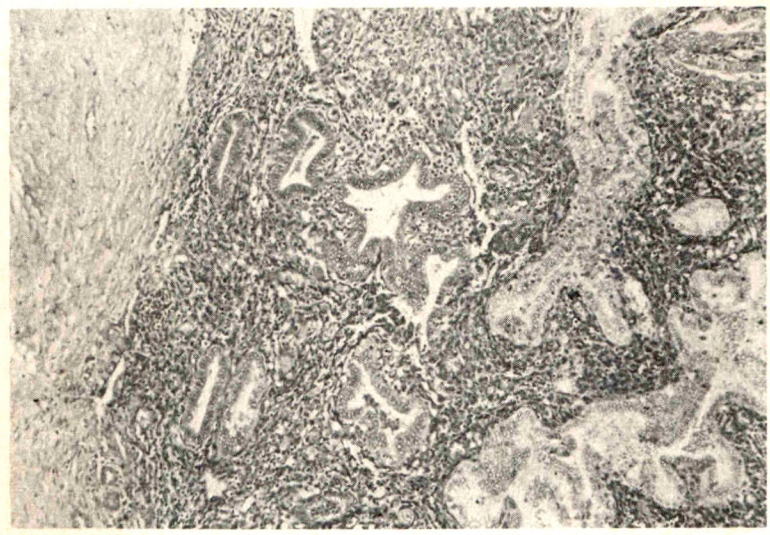

Fig. 3. Histologic preparation of hepatic cyst composed of fibrous wall and internal epithelial lining with endometrial glands and stroma in secretory phase. (Hematoxylin and eosin stain; original magnification ×28.8.)

segmentectomy was performed with removal of the entire cyst (Fig. 2). Gross examination showed a multilocular formation of endometriotic type with the typical dense chocolate-colored content. At histologic examination the cyst wall was lined by endometrial glands and stroma in secretory phase (Fig. 3).

In view of the histologic diagnosis, a gynecologic consultation was requested. The gynecologic history was negative. Pelvic exploration showed a nontender cystic mass at the left adnexal site, confirmed by ultrasonography. The patient underwent a second laparotomy and left adnexectomy was performed because of an ovarian endometrioma of 5 cm diameter. Small peritoneal endometriotic lesions were electrocoagulated.

Danazol 600 mg/day was prescribed postoperatively for 6 months. At 26 months of follow-up the patient was asymptomatic and neither physical examination

nor repeat pelvic and abdominal ultrasonography showed signs of disease recurrence.

Comment

The pathogenesis of a hepatic endometrioma is difficult to explain. The coexistence of pelvic endometriosis in our patient could suggest dissemination through the clockwise intraabdominal circulation of peritoneal fluid. On the other hand, endometrial cells are normally present in the physiologic retrograde menstruation, and even in cases of pelvic endometriosis upper abdominal lesions are extremely rare. In the embryo the paramesonephric ducts derive from an invagination of coelomic epithelium. Furthermore, this epithelium covers the hepatic "bud." Hepatic endometriosis could originate from a spread of müllerian cells in the cranial direction or possibly from coelomic metaplasia of the peritoneum covering the liver. The rarity of the lesion could be related to the distance from the internal genital system.[1]

According to the classification by Markham et al.,[1] our patient had class I endometriosis (involving the intestinal tract), stage I.2.c [no organ defect, intrinsic (parenchyma), >4 cm lesion]. We would not place her in class 0 because this refers to endometriosis that involves sites outside the abdominal cavity.

In view of the absence of pelvic symptoms in our patient and the extreme rarity of hepatic cyst of endometriotic origin, she did not undergo a preoperative gynecologic evaluation. The only other case of hepatic endometrioma reported in the literature of which we are aware presented no indications of associated genital lesions.[2] We believe that endometriosis should be included in the differential diagnosis of a hepatic cyst of unknown cause and that a gynecologic examination and pelvic ultrasonography should be performed before surgery is attempted.

Antinuclear antibodies in sera of patients with recurrent pregnancy wastage

Ling Xu, MD, Victoria Chang, BS, Ana Murphy, MD, John A. Rock, MD, Marian Damewood, MD, William Schlaff, MD, and Howard A. Zacur, MD, PhD
Baltimore, Maryland

Four groups of women were studied to determine whether low-level antinuclear antibody titers are associated with a higher risk for pregnancy loss. Group A consisted of 30 patients with a history of unexplained fetal losses. Group B consisted of 30 women with "explained" fetal losses (e.g., uterine septum or luteal phase defect). Ages and number of losses were comparable between the women in groups A and B. Group C consisted of 61 healthy pregnant women. Group D involved 61 healthy nonpregnant women of reproductive age. In groups A and B, 40% and 53.3% of the respective patients had antinuclear antibody titers ≥1 : 40. In groups C and D the frequencies of positive antinuclear antibody titers were 8.2% and 5.6%, respectively. This study demonstrates a high prevalence of low-titer antinuclear antibody–positive serum in patients with explained and unexplained pregnancy losses. (AM J OBSTET GYNECOL 1990;163:1493-7.)

Key words: Repeated pregnancy wastage or losses, habitual abortion, antinuclear antibody

Recurrent fetal wastage is common in women with systemic lupus erythematosus,[1-3] presenting even before the onset of clinical manifestations.[4, 5] Since antinuclear antibodies have been accepted as serologic markers for the presence of autoimmune disease,[6-8] the association between recurrent fetal wastage and serum antinuclear antibodies, especially in women who are asymptomatic of any autoimmune disease, has been investigated. No clear relationship has been established until recently when Garcia-De La Torre et al.[9] reported a 30% prevalence of antinuclear antibody-positive sera in patients with unexplained habitual abortions that was significantly greater than 6.6% prevalence in their control group with normal pregnancies. Cowchock et al.[10] reported positive antinuclear antibody titers in four of 14 patients with idiopathic habitual abortion but in only one of 16 patients whose repeated abortions had an explanation (i.e., uterine anomalies, chromosome abnormalities, or luteal phase defect). In a recent prospective study Farnam et al.[11] reported that the incidence of positive antinuclear antibody titers in pregnant women is significantly higher than in nonpregnant women and reaches its highest level at the end of pregnancy.

To determine whether positive antinuclear antibody titers are associated with a higher risk of recurrent fetal wastage or a physiologic change in normal pregnancy, we conducted a study to compare the prevalance of antinuclear antibody titers among patients with unexplained recurrent fetal wastage, patients with explained recurrent fetal wastage, women with normal pregnancy, and healthy nonpregnant women.

Material and methods

Subjects

Patient population. Patients in this study were referred to The Johns Hopkins Hospital from August 1984 to November 1987 for evaluation after at least two *consecutive* pregnancy losses. Clinical and laboratory evaluation in all patients included antinuclear antibody measurement, karyotypic analysis, hysteroscopy or hysterosalpingography, endometrial biopsy or progesterone determinations, and cervical cultures. Thyroid function studies, activated partial thromboplastin time, anticardiolipin panel, mixed lymphocyte culture, or human leukocyte antigen typing were not performed in all patients.

Thirty patients (group A) were identified as having unexplained recurrent fetal wastage because clinical and laboratory evaluation failed to reveal any cause for their pregnancy losses. The mean age of the group was 32.6 years (range, 21 to 38 years). The mean number

Table I. Possible causes of pregnancy losses in patients with repeated pregnancy losses

Causes	*No.*
Uterine abnormality	16
Luteal phase defect	6
Chromosome abnormality	1
Positive cervical culture	1
Hyperprolactinemia	1
Adrenal hyperplasia	1
Two or more causes combined	4
TOTAL	30

of pregnancy losses was 3.3 (range, 2 to 14). No patient had a history of autoimmune disease.

Another 30 patients (group B) were identified as having explained repeated pregnancy losses because their clinical and laboratory evaluation showed one or more of the following diagnoses: uterine abnormalities, chromosome abnormalities, luteal phase defects, positive cervical culture, or other endocrine and metabolic disorders (Table I). The mean age of this group was 30.4 years (range, 24 to 38 years), and the mean number of pregnancy losses was 2.8 (range, 2 to 6). None had a history of known autoimmune disease.

Normal pregnant population. Serum samples from 61 healthy pregnant women were obtained during routine prenatal visits to the obstetric clinic at The Johns Hopkins Hospital (group C). The mean age of this group was 23.2 years (range, 14 to 35 years). Eighteen women were in their first or second trimester, and 43 were in the third trimester of pregnancy when studied. Individuals with a known history of autoimmune disease were not included in this group.

Healthy nonpregnant population (control group). Sixty-one healthy nonpregnant women of reproductive age (15 to 40 years) were studied (group D). They were considered healthy because none of them had a history of known autoimmune diseases, metabolic disorders, or any chronic or current infectious diseases. These patients had been recruited for another clinical study of oral contraceptive therapy that had been approved by The Johns Hopkins Hospital Joint Committee on Clinical Investigation. None of these patients were taking oral contraceptives at the time of baseline blood sampling.

Antinuclear antibody determination. An indirect fluorescent antibody technique using HEp-2 cell culture and reagents supplied by Zeus Scientific, Inc. (Raritan, N.J.) was used for the antinuclear antibody screening. Sera with 1+ or greater fluorescence at a dilution of 1 : 40 were considered positive.

Statistical analysis. Statistical analysis was performed with the use of t tests for differences between means, and the use of χ^2 statistic with correction for continuity. Significance was determined at a probability level of 0.05 for two-tailed test.

Results

Table II demonstrates the frequency of antinuclear antibody–positive sera in each study group. The frequency of positive antinuclear antibody titers in sera of 30 patients with unexplained repeated pregnancy losses was 40% in comparison with only 5% in 61 healthy nonpregnant women. This difference was statistically significant ($\chi^2 = 15.19$, df = 1, $p < 0.01$). The frequency of antinuclear antibody–positive sera in 30 patients with explained repeated pregnancy losses was 53%; this incidence was also significantly different from the control group ($\chi^2 = 25.42$, df = 1, $p < 0.01$). No significant difference in the frequency of antinuclear antibody–positive sera between patients with explained or unexplained pregnancy losses was found. The mean age and mean frequency of pregnancy losses were also compared between antinuclear antibody–positive patients and antinuclear antibody–negative patients in both explained and unexplained recurrent fetal wastage groups. No significant differences were found (Table III).

In the group of 61 healthy pregnant women (group C) the frequency of antinuclear antibody–positive sera was 8%. Table II shows that there was no significant difference in the frequency of antinuclear antibody–positive sera between normal pregnant women and healthy nonpregnant women (group D) ($\chi^2 = 0.4$, df = 1, $p > 0.05$). Gestational age did not correlate with antinuclear antibody–positive sera (Table IV). Comparison of antinuclear antibody–positive sera between nonpregnant women, pregnant control women, women with unexplained repeated pregnancy losses, and explained pregnancy losses showed no effect of age (Tables III and V).

Comment

It has been recognized that women with autoimmune disease have an increased frequency of pregnancy losses. The recognition of this association has led to general recommendations to screen patients with recurrent fetal wastage for autoimmunity. Reports on the association between recurrent fetal wastage and positive antinuclear antibody titers from several recent studies are controversial. In this study four population groups were examined for the frequency of antinuclear antibody–positive sera, and the differences among these groups in terms of antinuclear antibody–positive sera were compared.

The question of whether recurrent fetal wastage is associated with certain autoimmune disorders has been investigated. Garcia-De La Torre et al.[9] reported that the prevalence of antinuclear antibodies was signifi-

Table II. Frequency of antinuclear antibody–positive sera in each study group

Groups	No.	Antinuclear antibody–positive*		Significance test
		n	%

Normal pregnancy	61	5	8.2	$p > 0.05$ ($\chi^2 = 0.14$)
Explained recurrent fetal wastage	30	16	53.3	$p < 0.01$ ($\chi^2 = 25.42$)
Unexplained recurrent fetal wastage	30	12	40	$p < 0.01$ ($\chi^2 = 15.80$)

*Positive antinuclear antibody sera defined as having a titer of ≥1:40.

Table III. Comparison of selected variables between antinuclear antibody–negative and antinuclear antibody–positive patients with explained or unexplained recurrent fetal wastage

Variables	Explained recurrent fetal wastage			Unexplained recurrent fetal wastage		
	Antinuclear antibody–negative	Antinuclear antibody–positive	p	Antinuclear antibody–negative	Antinuclear antibody–positive	p
Age (yr) (mean ± SD)	29.4 ± 9.0	29.9 ± 4.0	>0.80	32.6 ± 3.1	31.6 ± 4.7	>0.80
No. of pregnancy losses (mean ± SD)	3.1 ± 1.0	2.5 ± 0.6	>0.05	3.4 ± 2.8	3.3 ± 1.1	>0.80
Frequency of primary recurrent fetal wastage (%)	85.7	93.6	>0.40	72.2	83.3	>0.50

Positive antinuclear antibody sera defined as having a titer of ≥1:40.

Table IV. Association between serum-positive antinuclear antibody and gestational age in normal pregnancy

Gestational age (wk)	No.	Antinuclear antibody–positive		p
		n	%	
<28	18	1	5.60	>0.03
>28	43	4	9.30	
TOTAL	61	5	8.20	

cantly greater in patients with unexplained habitual abortion than in women with normal pregnancies. In a recent controlled prospective study, Petri et al.[12] found that patients with idiopathic habitual abortion did not differ from normal control subjects in the frequency of positive titers for antinuclear antibodies or anti-double-stranded deoxyribonucleic acid. In our investigation antinuclear antibody–positive sera were found in 40% of 30 patients with unexplained recurrent fetal wastage and in 53% of 30 patients with explained pregnancy losses. In comparison, only three (5%) of 61 nonpregnant women and five (8%) of 61 pregnant women had positive antinuclear antibody titers. The differences are statistically significant not only between patients with recurrent fetal wastage and nonpregnant control women, but also between women with recurrent fetal wastage and normal pregnant women. Age did not affect these results. Therefore a positive correlation between pregnancy losses and frequency of antinuclear antibody–positive sera was revealed.

A comparison between patients with unexplained recurrent fetal wastage and patients with explained recurrent fetal wastage was performed. These women were similar in age and number of pregnancy losses. The frequency of antinuclear antibody–positive sera was 40% in cases of unexplained recurrent fetal wastage and 53% in women with explained recurrent fetal wastage. The difference was not significant ($p > 0.05$). Cowchock et al.[10] also reported no difference in rates of antinuclear antibody–positive sera in patients with unexplained recurrent fetal wastage compared with patients with explained recurrent fetal wastage. Because

Table V. Relative odds and age-adjusted relative odds for antinuclear antibody–positive sera

Group	*Odds ratio*	*95% Confidence interval*	*Age-adjusted odds ratio*	*95% Confidence interval*
Normal control	1			
Normal pregnancy	2.7	0.5-14.8	2.0	0.3-13.3
Unexplained recurrent fetal wastage	10.0	2.0-50.1	10.3	1.6-63.6
Explained recurrent fetal wastage	22.7	4.6-112.2	26.6	4.9-145.8

the cause of fetal wastage is complex and undoubtedly multifactorial, other autoimmune disorders could be responsible for repeated pregnancy losses; this may explain the difference between our results and those of other investigators.

We attempted to determine if the presence of serum-positive antinuclear antibodies is a physiologic change of normal pregnancy. Most investigators have found that pregnancy is one factor that may cause exacerbation of systemic lupus erythematosus. Many autoimmune diseases such as systemic lupus erythematosus, progressive systemic sclerosis, autoimmune hemolytic anemia, and autoimmune thrombocytopenia are exacerbated during pregnancy. The association between pregnancy and serum antinuclear antibody has been reported from several studies. Farnam et al.[11] found that antinuclear antibody was detected in 23 of 214 healthy pregnancy women (10.7%), but in only one nonpregnant woman of 50 was antinuclear antibody sera positive (2%). Polishuk et al.[13] reported that serum-positive antinuclear antibody was present in 52.2% of normal pregnant women in comparison with 9.1% of controls. Our investigation revealed no significant difference in the frequency of antinuclear antibody positivity between normal pregnant women (8%) and healthy nonpregnant women (5%), $p > 0.05$; and this concurs with other recent reports.[14,15] Unlike the finding in the study by Farnam et al.,[11] we failed to find an increasing frequency of antinuclear antibody positivity in serum taken from pregnant women later in pregnancy.

Finally, we examined whether other factors were associated with antinuclear antibody–positive sera in patients with recurrent fetal wastage. Cowchock et al.[16] reported that an increased frequency of antinuclear antibody–positive sera was not found in patients with two or more pregnancy losses. We are in agreement with these findings because in our study mean age, order or number of pregnancy losses, and number of previous induced abortions did not affect the frequency of antinuclear antibody–positive sera in women with unexplained or explained recurrent fetal wastage. Our results suggest that a screening test for antinuclear antibodies in patients with recurrent fetal wastage should be considered. Further observations on both the pregnancy outcome and medical course of patients with positive screening studies will be necessary since the clinical significance of the positive antinuclear antibody titer remains to be determined. It also remains unclear whether the positive antinuclear antibody titer preceded or followed the pregnancy losses.

We thank Mrs. Kathy Zulty for her excellent editorial assistance.

Corpus luteum function in early pregnancies is primarily determined by the rate of change of human chorionic gonadotropin levels

Paul G. Kratzer, MD, PhD, and Robert N. Taylor, MD, PhD
San Francisco, California

Regulation of human corpus luteum activity was studied with radioimmunoassays and bioassays of sera drawn serially from women suspected of having ectopic pregnancies. Progesterone values exhibited considerable overlap in pregnancies that were subsequently classified as normal intrauterine (n = 21), ectopic (n = 35), or spontaneous abortion (n = 14). The rate of change of human chorionic gonadotropin concentration was significantly correlated with progesterone levels in ectopic (r = 0.64) and all pregnancies (r = 0.70). There was no correlation (r = −0.18) between the rate of change of human chorionic gonadotropin and the bioactivity produced per volume of serum. Ectopic pregnancies and normal intrauterine pregnancies did not differ in their ratio of in vivo bioactivity to immunoactivity. From these data we conclude that corpus luteum activity is primarily regulated by the rate of change of human chorionic gonadotropin concentration, without the involvement of other serum factors. We also conclude that reduced corpus luteum function in ectopic pregnancies is not a result of biochemical modification of the human chorionic gonadotropin molecule. Finally, we discourage the use of single progesterone values in screening for ectopic pregnancies because of the considerable overlap in progesterone values among these and normal intrauterine pregnancies. (AM J OBSTET GYNECOL 1990;163:1497-502.)

Key words: Corpus luteum, ectopic pregnancy, chorionic gonadotropin, progesterone

The human corpus luteum is formed from the remnants of the postovulatory ovarian follicle. An important function of the corpus luteum is the synthesis of progesterone. Progesterone synthesized from the corpus luteum is required for the maintenance of normal pregnancy for the first 7 weeks' gestation.[1]

6/1/24144

The placental syncytiotrophoblast synthesizes increasing amounts of progesterone, such that by 8 1/2 weeks the placenta and corpus luteum contribute equal amounts of progesterone and the placental contribution alone is sufficient to maintain pregnancy.[1] Overall, the level of progesterone normally increases for the first 2 weeks after conception while luteinization is prominent, and then slightly decreases or remains approximately constant until the luteoplacental shift.[2-4]

The regulation of the corpus luteum is poorly understood. Human chorionic gonadotropin (hCG) administered to nonpregnant women in the luteal phase prolongs the life of the corpus luteum[5-8] and enhances the production of progesterone.[9] However, a simple dose-response relationship does not exist for hCG as evidenced by the relatively constant progesterone levels in early normal intrauterine pregnancies in which the

hCG levels vary remarkably. Abnormalities of early human pregnancy and placentation, such as ectopic pregnancy and spontaneous abortion, provide opportunities to evaluate corpus luteum pathophysiology.

In ectopic pregnancies the progesterone levels are generally lower than in normal intrauterine pregnancies.[10,11] However, these lower progesterone levels are not a result of the lower absolute hCG levels that are found in ectopic pregnancies, inasmuch as when ectopic pregnancies and intrauterine pregnancies with similar hCG levels were compared, the progesterone levels in ectopic pregnancies were still lower.[12] The cause of the lower progesterone levels in ectopic pregnancies could be explained by several possible mechanisms: (1) ectopic pregnancies might synthesize an inferior quality hCG, perhaps as a result of aberrant glycosylation, thereby rendering it less efficient in the stimulation of corpus luteum production of progesterone; (2) a specific factor(s) other than hCG might be responsible for corpus luteum stimulation and this factor(s) could be deficient in ectopic pregnancies; (3) corpus luteum activity might be dependent on the rate of hCG production, which is lower in ectopic pregnancies.[13]

As a consequence of the lower progesterone levels noted in ectopic pregnancies, it has been proposed that ectopic pregnancies could be distinguished from normal intrauterine pregnancies on this basis.[12,14-17] We have studied a population of women who were first seen in subacute condition and had serial blood samples drawn as part of an evaluation to rule out ectopic pregnancy. Analysis of these samples allowed us to assess the basis of corpus luteum regulation and to evaluate the reliability of a single progesterone value in screening for ectopic pregnancies.

Material and methods

Patients. Seventy patients were identified retrospectively from 1986 to 1990 who were first seen at either Moffitt Hospital or San Francisco General Hospital within the first 10 weeks' gestation (5.6 ± 0.2 weeks, mean ± SE) in subacute condition with signs and symptoms that were suspicious for ectopic pregnancy. All patients had conceived after spontaneous ovulation and had not received postconceptional hormone support. Part of the management of these patients consisted of serial hCG levels drawn over several days. The sera were subsequently stored at −20° C. The patients were ultimately classified into three groups by subsequent outcome: (1) ectopic pregnancy verified by pathologic examination of the surgical specimen, (2) viable intrauterine pregnancy verified by follow-up prenatal care to at least midgestation, or (3) clinical spontaneous abortion.

Assays. The frozen sera were evaluated with the following assays. The hCG was assayed by a double-antibody radioimmunoassay that detected total β-hCG. The hCG levels were expressed as milliinternational units (mIU) with the Second International Standard for hCG. The intra- and interassay coefficients of variation were 8% and 14%, respectively. Progesterone was assayed after hexane extraction with a standard radioimmunoassay with intra- and interassay coefficients of variation of 9% and 12%, respectively. In vivo bioactivity of hCG was determined with a mouse uterine weight assay.[18] Serum from each patient was serially diluted in saline solution after normalizing to a constant concentration by radioimmunoassay. The patients' sera were then injected intraperitoneally into 4-week-old Balb/c female mice on three successive days. On the fourth day the mice were killed. Each uterus was dissected free of the cervix, oviducts, and mesenteries, incised longitudinally, blotted dry, and then weighed. Uterine weight increased linearly from 10 to 50 mg with hCG concentration over the range of 15 to 100 mIU/ml using Profasi hCG (Serono Laboratories, Randolph, Mass.) as a standard. The bioactivity to immunoactivity ratio of serum hCG from each patient was determined by comparison of the slope of the curve to that of the standard hCG curve. The intra- and interassay coefficients of variation of the bioactivity to immunoactivity ratio were 19% and 21%, respectively. The mouse bioassay was conducted in accordance with the guidelines outlined in the JOURNAL and with permission of the University of California, San Francisco Committee on Animal Research.

Calculation of the rate of change of hCG. The rate of change of hCG was determined from the slope of the curve generated by plotting hCG concentration versus date and time of serial blood samples drawn at 2- to 3-day intervals. The rate of change was expressed as the number of hCG doublings per day, which is the reciprocal of the doubling time. By so expressing the rate of change, a continuum of negative-to-positive changes could be plotted, representing decreasing and increasing hCG concentrations, respectively. This method of expressing the rate of change rather than as the doubling time avoids the discontinuity in the plot that would otherwise occur for the situation when there is no change in hCG concentration.

Statistics. Differences between patient groups were assessed with the two-tailed, unpaired Student t test, with $p < 0.05$ indicating significance.

Results

The rate of change of hCG is expressed as the number of hCG doublings per day, which is the reciprocal of the doubling time. In agreement with previously

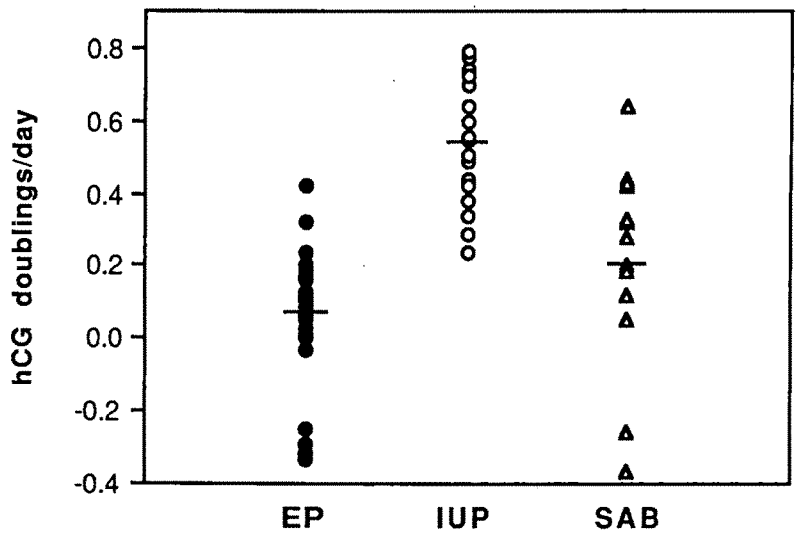

Fig. 1. Number of hCG doublings per day for individual samples from ectopic pregnancies (*EP*, •), normal intrauterine pregnancies (*IUP*, ○), and spontaneous abortions (*SAB*, △). Means for each group are indicated by *horizontal bars*. Mean rate for ectopic pregnancies was significantly less than that for intrauterine pregnancies ($p < 0.05$, by Student t test).

published results, the rate of change of hCG was significantly lower in ectopic pregnancies than that in normal intrauterine pregnancies (0.07 ± 0.03 hCG doublings per day vs 0.56 ± 0.04 hCG doublings per day, $p < 0.05$) with an intermediate rate determined for spontaneous abortions (0.21 ± 0.07 hCG doublings per day). The rates for individual samples are displayed in Fig. 1 and it is seen that samples from intrauterine pregnancies, spontaneous abortions, and ectopic pregnancies have overlapping values. Of ectopic pregnancies, 5/35 had a number of hCG doublings per day that equaled or exceeded the lowest rate observed in a normal intrauterine pregnancy (0.24 hCG doublings per day). Half the spontaneous abortions also had rates approximating those of the normal pregnancies.

Mean progesterone values were also significantly lower in ectopic pregnancies than in intrauterine pregnancies (10.5 ± 1.2 vs 29.2 ± 2.4 ng/ml, $p < 0.05$) and again were intermediate in spontaneous abortions (17.2 ± 3.1 ng/ml). It is apparent from Fig. 2 that there was considerable overlap among individual samples from intrauterine pregnancies, spontaneous abortions, and ectopic pregnancies. With various progesterone cutoff levels, 9/35 ectopic pregnancies had progesterone levels >15 ng/ml, a level that all normal intrauterine pregnancies exceeded, whereas 6/35 ectopic pregnancies had progesterone levels >20 ng/ml compared with 16/21 normal intrauterine pregnancies. For pregnancies resulting in spontaneous abortions, 8/14 had progesterone levels <20 ng/ml and 5/14 had progesterone levels <15 ng/ml.

The progesterone levels for individual patients were correlated significantly with an increasing number of hCG doublings per day in ectopic pregnancies ($r = 0.64$) and for all pregnancies ($r = 0.70$) as shown in Fig. 3. In contrast, there was no correlation between progesterone levels for individual patients and the absolute level of hCG for all pregnancies ($r = 0.02$). If we consider only those pregnancies in which serum samples were obtained at ≤7 weeks' gestation (i.e., before the luteoplacental transition begins), the correlation between progesterone levels and hCG doublings remains high for ectopic pregnancies ($r = 0.78$, $n = 20$) and for all pregnancies ($r = 0.67$, $n = 52$). Thus our findings do not appear to be skewed by placental steroidogenesis.

The mean bioactivity to immunoactivity ratio was not different among 12 ectopic pregnancies and 12 normal intrauterine pregnancies (9.2 ± 0.8 vs 7.7 ± 1.3, $p > 0.1$) (Table I). Likewise, when the bioactivity was considered per volume of serum, there was no correlation with the rate of change of hCG for either ectopic pregnancies alone ($r = -0.17$) or for ectopic pregnancies and intrauterine pregnancies ($r = -0.18$).

Comment

Corpus luteum function is required to maintain the early pregnancy until the luteoplacental shift begins at approximately 7 weeks' gestation.[1] Administration of hCG to nonpregnant women during the luteal phase stimulates corpus luteum activity[5-8] and prolongs its life span.[9] The role of hCG is unclear because there is no simple dose-response relationship. Possibilities include a requirement for the presence of an appropriate rate

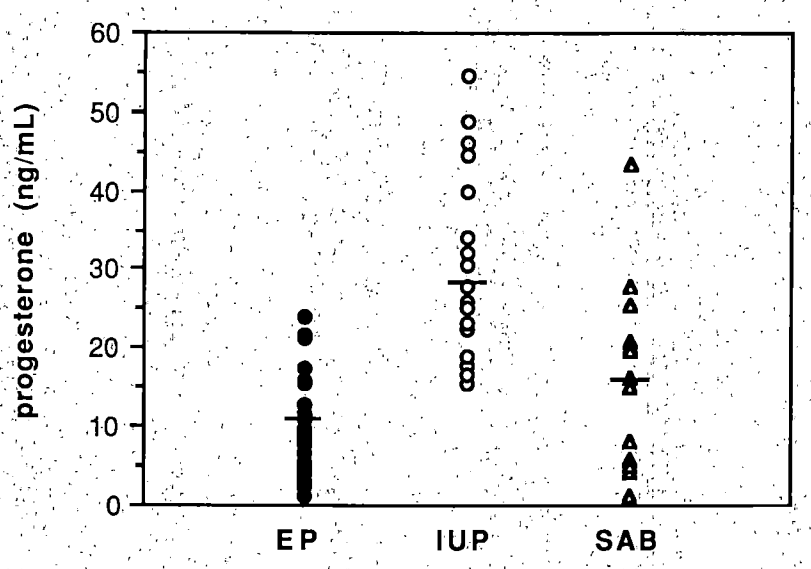

Fig. 2. Progesterone values (ng/ml) for individual samples from ectopic pregnancies (*EP*, •), normal intrauterine pregnancies (*IUP*, ○), and spontaneous abortions (*SAB*, △). Means for each group are indicated by *horizontal bars*. Mean progesterone value for ectopic pregnancies was significantly less than that for intrauterine pregnancies ($p < 0.05$, by Student t test).

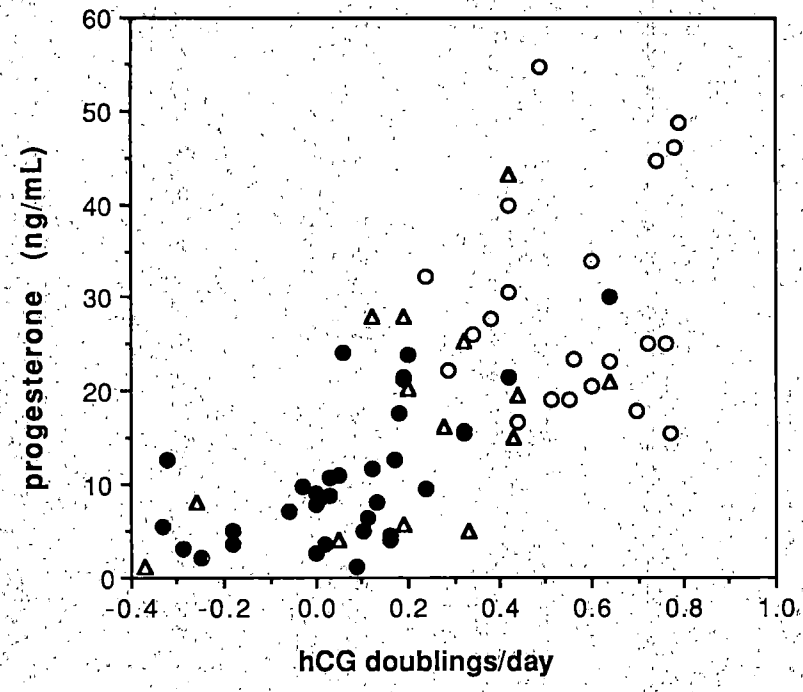

Fig. 3. Number of hCG doublings per day plotted against progesterone values (ng/ml) for individual samples from ectopic pregnancies (•), normal intrauterine pregnancies (○), and spontaneous abortions (△). Positive correlations were observed when all samples were considered ($r = 0.70$) and when ectopic pregnancies were considered separately ($r = 0.64$).

of change of hCG or another factor besides hCG that correlates with hCG. In this article, which expands on our preliminary report (Kratzer and Taylor, Proceedings of the forty-fifth meeting of the American Fertility Society, 1989:102), we show that corpus luteum activity is significantly correlated with the rate of change of hCG. The correlation of progesterone level with the rate of change of hCG obtains for all pregnancies in our study and most importantly it obtains in pregnancies before the luteoplacental shift when progesterone

levels overwhelmingly reflect the activity of the corpus luteum.[1] This correlation is not surprising in light of the lower progesterone levels in ectopic pregnancies[10, 11] and the lower rate of change of hCG in ectopic pregnancies[13] compared with normal intrauterine pregnancies. The possibility that another factor is involved in corpus luteum regulation can be excluded to a large extent by the following argument. If another factor were important in corpus luteum regulation, then it must be correlated with the rate of change of hCG, so that sera from patients with more rapidly increasing hCG should produce a greater response per volume of serum in the bioassay. However, no such correlation exists. Our bioassay was a heterologous system that used the mouse uterus. It is conceivable, albeit unlikely, that a factor other than hCG might exist that is functional in human beings, but not in the mouse. Except for this caveat, corpus luteum function is primarily regulated by the rate of change of hCG production.

Dependency of corpus luteum activity on the rate of change of hCG, rather than on its absolute concentration, explains why normal early intrauterine pregnancies of different ages and widely different hCG concentrations, but all with rapidly increasing hCG levels, have similar progesterone levels. The dependency of corpus luteum activity on the rate of change of hCG also explains why ectopic pregnancies and spontaneous abortions often have lower progesterone levels than normal intrauterine pregnancies, as the former generally have less rapidly increasing hCG levels. Dependency on the rate of change of hCG also explains why there is only limited prolongation of corpus luteum life span in nonpregnant women after chronic administration of a constant dose of hCG.[9] In the monkey, chronic administration of a constant dose of hCG also results in only limited prolongation of the corpus luteum.[19] However, it has been found that corpus luteum life span can be extensively prolonged by continuously increasing the hCG dose in the early luteal phase.[20]

The mechanism by which the rate of hCG presentation regulates corpus luteum function may involve the number and percentage of bound luteinizing hormone/hCG receptors on the corpus luteum. In early human pregnancy, the number of unbound luteinizing hormone/hCG receptors is low and increases in the first trimester.[21] This low number of unbound receptors is a result of a high receptor occupancy rate[22, 23] rather than a result of down regulation in the total number of receptors.[23] In persistently stimulated monkey corpus luteum likewise, both the number of occupied receptors and total number of receptors increases, whereas the number of unoccupied sites remains unchanged.[24] We propose that in the first 2 weeks' gestation, the percentage of ligand-bound receptors on the corpus luteum increases from a very small percentage to a percentage at which maximal stimulation is achieved and that the number of these receptors increases as a result of corpus luteum growth and maturation. An increasing number of luteinizing hormone/hCG receptors on the corpus luteum cells would require that hCG concentrations increase at a sufficient rate to maintain optimal receptor occupancy. By this mechanism, maximal corpus luteum stimulation would be achieved only when hCG production increased commensurately with the number of receptors.

Table I. Bioactivity/immunoactivity ratio in ectopic pregnancies and normal intrauterine pregnancies

Sample	*Number*	*Ratio**
Ectopic pregnancy	12	9.2 ± 0.8
Normal intrauterine pregnancy	12	7.7 ± 1.3

*Bioactivity/immunoactivity ratio values are expressed as the mean ± SE. The difference between the means was not significant ($p > 0.1$, by the Student t test).

In ectopic pregnancies, the lower progesterone levels could result solely from a decreased rate of change of hCG, or could be partly a result of decreased biopotency of hCG or the lack of another factor. As argued previously, it is doubtful that there is another factor that is lacking. Reduced biopotency of the hCG molecule in ectopic pregnancies compared with that in normal intrauterine pregnancies has not been found in either heterologous (mouse Leydig cell) in vitro bioassays,[25, 26] or in homologous (human granulosa cell) in vitro bioassays (Kratzer, Rabinovici, and Taylor, unpublished results). The absence of a difference in these in vitro bioassays suggested that altered glycosylation of hCG does not explain the impaired corpus luteum function in ectopic pregnancies. Our in vivo bioassay could have detected additional modifications of hCG molecules, such as sialylation, that would affect its half-life. The lack of a difference in hCG bioactivity between ectopic pregnancies and intrauterine pregnancies in our in vivo bioassay therefore mitigates against post-translational modifications of hCG in ectopic pregnancies such as glycosylation and sialylation. Therefore in ectopic pregnancies impaired hCG production by the abnormally implanted trophoblast appears to be primarily responsible for the inability of the corpus luteum to maintain optimal function.

Ectopic pregnancies are increasing in frequency and represent a potential threat to the mother's life and future fertility.[27] Classically, surgery has been used for the diagnosis and treatment of ectopic pregnancies first seen in an acute condition, whereas protocols that involve serial hCG determinations and ultrasonographic evaluation have been used in the diagnosis of those first

seen in a subacute condition. Recently, the use of single progesterone values has been advocated to screen for ectopic pregnancies with progesterone cutoffs of 20 ng/ml,[16] 15 ng/ml,[12, 15] 10 ng/ml,[14] or 6.5 ng/ml.[17] It was further recommended that patients with progesterone levels below these cutoffs should undergo uterine curettage for a presumed abnormal pregnancy, and if no villi were found in the curettings that laparoscopy or methotrexate therapy be instituted.[15,17] On the basis of the findings reported here, we discourage the use of single progesterone levels to screen for ectopic pregnancies because a considerable number of ectopic pregnancies would be missed and these would still need to be followed by serial hCG levels with the current protocols. Moreover, the possibility of inadvertently mistaking an early, normal intrauterine pregnancy with a low progesterone value for an abnormal pregnancy, and consequently terminating such a pregnancy, is disconcerting. To avoid this type of error, the cutoff would have to be set so low that screening with progesterone would identify too few ectopic pregnancies to be of value.

We thank Dr. Scott Monroe and Mary Tono for their generous help with specimen collection and Carmelita Aquirre and Steven Zippin for their excellent technical assistance.

Hemoperitoneum as a result of coital injury without associated vaginal injury

Sterling W. McColgin, MD,[a, b] Lisa M. Williams, MD,[b] Timothy L. Sorrells, MD,[a] and John C. Morrison, MD[b]

Travis Air Force Base, California, and Jackson, Mississippi

Hemoperitoneum as a result of coital injury without associated vaginal injury is an extremely rare entity, and evidenced by only five cases that have been reported in the medical literature to date. We report five additional cases encountered in two medical centers. Two of these were ruptured corpus luteum cysts, one was a laceration of the round ligament, another was a laceration of an ovary, and the fifth was rupture of a serous cystadenoma. This diagnosis should be considered in patients with hemoperitoneum after coitus. (Am J Obstet Gynecol 1990;163:1503-5.)

Key words: Hemoperitoneum, coital unjury, culdocentesis

Since 1907, 232 cases of significant female coital injuries were found in the medical literature.[1-15] Of these, there were only five reported cases of hemoperitoneum caused by coital injury without associated vaginal injury. Five additional cases of this most unusual entity were diagnosed and treated by us. All of these additional patients had normal results of vaginal examination.

Case reports

A 31-year-old woman, para 3-0-0-3, had sudden onset of lower abdominal pain during coitus on the evening before admission. The pain had increased and by morning radiated to her back and shoulders. Her last menstrual period was 3 weeks before admission. She had undergone a postpartum tubal ligation with her last cesarean delivery. The serum human chorionic gonadotropin level was normal. Abdominal examination revealed diffuse tenderness with mild bilateral rebound and normal bowel sounds. Pelvic examination revealed no trauma to the vagina; the uterus was of normal size with moderate bilateral adnexal tenderness. Culdocentesis produced 10 ml of nonclotting thin, bloody fluid. The diagnosis of ruptured follicular cyst was made. Vital signs were evaluated frequently, and serial hemoglobin and hematocrit levels were determined. Because of a decline in the hemoglobin from 11.2 to 8.7 gm/dl, an exploratory laparotomy was performed. At exploration, a hemoperitoneum was encountered. The tubes, ovaries, and uterus were grossly normal except for evidence of the previous tubal ligation. No adhesions were noted. Further inspection revealed a 2 to 3 cm laceration of the right round ligament with active arterial bleeding. Hemostasis was obtained with figure-of-eight sutures. After an uneventful postoperative course, she was discharged on the fifth postoperative day.

A 30-year-old woman, para 0-1-4-1, presented to our emergency room with a 5-hour history of abdominal pain that started 3 hours after coitus and gradually worsened. Her last menstrual period was 3 weeks before admission, and she was not using any contraceptive measures. Her history was significant for use of an intrauterine contraceptive device, gonorrhea with subsequent pelvic inflammatory disease, and two previous cesarean sections. On evaluation, the patient was noted to have an acute abdomen and a negative serum pregnancy test result. An exploratory laparotomy was performed with findings of 500 ml of blood intraabdominally and a 2.5 cm laceration on the right ovary. There was no evidence of adhesive disease or pelvic inflammatory residual intraabdominally at the time of operation. The laceration was repaired with interrupted sutures. She was discharged on the fourth postoperative day without complications.

Two hours after coitus, a 36-year-old woman presented to our emergency room with the onset of sudden sharp and increasing abdominal pain radiating to the right shoulder. She had a tubal ligation in 1975 and a hysterectomy and appendectomy in 1981. On evaluation, she had a positive psoas sign and was believed to have an acute abdomen. An exploratory laparotomy was performed with findings of 1000 ml of blood in the abdomen and a 3 cm ruptured ovarian cyst that was adherent to the left pelvic sidewall. A left salpingo-oophorectomy was performed. Numerous bowel and

pelvic adhesions were noted intraoperatively and were lysed. Her postoperative course was complicated because of chronic obstructive pulmonary disease and postoperative pneumonia. She was discharged on the eleventh postoperative day. Pathologic diagnosis of the ovary revealed a serous cystadenoma that had ruptured.

A 25-year-old woman, para 2-0-0-2, noted the onset of sudden suprapubic pain with radiation to the right lower quadrant and right shoulder during coitus. During evaluation, a bulging cul-de-sac was noted and culdocentesis resulted in 15 ml of nonclotting blood. She was orthostatic at the time of evaluation and immediately given fluid for resuscitation and prepared for operation. She had never been hospitalized except for two spontaneous vaginal deliveries. An exploratory laparotomy was performed and 350 ml of blood and blood clot was found in the abdomen. In addition, a bleeding corpus luteum cyst was noted at the distal pole of the left ovary. A wedge resection was performed and hemostasis was ascertained. The other ovary was normal and there was no evidence of prior pelvic infection, adhesions, or endometriosis. She was discharged on the fourth postoperative day after an uneventful postoperative course.

A 24-year-old, nulliparous patient presented to the emergency room with bilateral lower quadrant pain. During coitus on the evening of admission, the patient noted a dull aching pain deep inside the pelvis and on withdrawal felt a severe pain "like a balloon inside bursting." The pain continued to worsen with localization to the right lower quadrant. Previous surgery included a diagnostic laparoscopy for an infertility evaluation with negative findings. Her history was also positive for severe dysmenorrhea. The patient was admitted and underwent a diagnostic laparoscopy. An active bleeding site was seen on the right ovary, and at subsequent laparotomy a ruptured hemorrhagic corpus luteum cyst was wedged resected. The other adnexa and the uterus were normal, and there was no evidence of previous gynecologic disease. She was discharged on the fifth postoperative day after an uncomplicated postoperative course.

Comment

The pelvic organs are well suited for intercourse and coital injuries are believed to be unusual. Until the end of the nineteenth century, it was doubted that lesions could occur at all during coitus that took place with the common consent of both parties.[8] This premise was disproved by Neugebauer[16] in 1895, who showed that the mere insertion of the penis during intercourse can cause lesions in all parts of the vulva and vagina, including the vault.

Most reviews of coital trauma and discussions of the etiologic factors involved limit their discussions to vaginal and perineal injuries. Reported predisposing factors include (1) pregnancy—with the increased friability of the tissues and fixation of the genital tract coincident with gestation; (2) vigorous intercourse, which may cause increased intraabdominal pressure in the female partner and may tend to make the cul-de-sac tense and lessen the elasticity of the posterior fornix during deep penetration; (3) coital positions in which unusually deep penetration is experienced, such as the dorsal decubitus position with hyperflexion of the thighs and the sitting positions; (4) vaginismus, which may cause injury by shortening and narrowing of the vaginal tube; (5) genital disproportion, particularly in prepubertal girls and young women at first intercourse; (6) postmenopausal atrophy caused by increased friability and shortening of the vagina; (7) genital operations or injuries with disruption of the vaginal vault suture lines and/or shortening of the vagina; (8) uterine retroversion; and (9) rape.[5, 6, 17]

Lower vaginal injuries are more often seen in young women as a result of rape or first intercourse whereas tears of the vaginal vault are usually found in multiparous women. Both of these injuries can be very severe and cause perforation, subsequent bleeding in the peritoneal cavity, and even death.[4, 5, 7]

Only five cases of hemoperitoneum without perforation were found in the medical literature. Three of these were summarized by Engel[7] and included two lacerations of the left broad ligament and a higher parametrial laceration. Madej et al.[11] reported the fourth case, which was associated with a rupture of a corpus luteum cyst. A case report of bleeding caused by adhesive disease after coitus was reported in this country in 1986.[15] An interesting case of postcoital pneumoperitoneum 2 months after abdominal hysterectomy has been reported by Apesos et al.[14]

Dickinson[18] describes female genital injuries as being more common on the right because of dextrorotation of the uterus and an increased distensibility of the vagina in this area. Indeed three of the five cases reported here involved injuries on the right. It is conceivable that a combination of pelvic adhesions and vigorous deep thrusting could cause the injuries reported, but adhesions were present in only one of five patients reported on in this series. The cause of these other injuries remains obscure. In our cases no patient could recall any trauma during coitus that might have accounted for these intraabdominal injuries. Nevertheless practitioners should have a high index of suspicion of coital trauma even when examination of the vagina and external genitalia is unrevealing. While the incidence of postcoital bleeding from ligament or ovarian damage may, in fact, be rare, it is likely that postcoital trauma resulting in hemoperitoneum in association with rupture of corpus luteum cysts, ectopic pregnancies, and other ovarian lesions has previously been underreported.

Postmortem chorionic villus sampling is a better method for cytogenetic evaluation of early fetal loss than culture of abortus material

Mark Paul Johnson, MD, Arie Drugan, MD, Frederick C. Koppitch III, MS, Wendy R. Uhlmann, MS, and Mark I. Evans, MD

Detroit, Michigan

In utero chorionic villus sampling at the time of diagnosis of intrauterine fetal death is compared with more traditional use of cultured fetal skin, products of conception, or amniocentesis. A total of 102 specimens from early fetal losses were evaluated for success in karyotyping and chromosomal results. We found postmorten chorionic villus sampling is technically possible, offers the highest likelihood of getting a cytogenetic result, and is a rapid, reliable, and safe technique. The extraembryonic component of intrauterine fetal deaths appears to remain viable and continues to grow long after the embryo has died. Samples obtained at the time of diagnosis of fetal death offer the greatest changes of successfully obtaining a karyotype. The incidence of chromosome abnormalities associated with fetal loss, particularly trisomies, is higher than previous data suggested. (AM J OBSTET GYNECOL 1990;163:1505-10.)

Key words: Abortion, pregnancy loss, chorionic villus sampling, amniocentesis

The degree of embryonic and fetal wastage in human beings has been found to be high. Several studies have suggested that 50% to 80% of fertilized ova are lost before reaching the second trimester. Chromosomal abnormalities are a significant factor in fetal loss, and rates of occurrence vary. Hook et al.,[1] predicted that at least 5% of conceptions as early as 5 weeks could be expected to be karyotypically abnormal. Warburton et al.,[2] postulated that 10% to 50% of all human conceptions may have an identifiable chromosomal defect.

Cytogenetic evaluation of embryonic or fetal loss has been hindered in the past by the poor success rate of obtaining viable cells for culture and successfully ob-

taining karyotyping. Successful karyotypes are obtained in spontaneously aborted tissues only approximately 50% of the time.[2] Other tissue sources were used from spontaneous abortions with improved success (Table I). These data suggest that the extraembryonic compartment may remain viable for a period of time after embryonic or fetal loss, and that those were the tissues that were most likely to be successfully cultured.

Along with other prenatal centers, we have been frustrated by the poor success rates in obtaining karyotypes in cases of fetal loss. Thus we began to try and herein report on the use of in utero chorionic villus sampling at the time of diagnosis of intrauterine fetal death as compared with the more traditional use of cultured fetal skin, products of conception, or amniocytes obtained by amniocentesis in cases of fetal loss.

Material and methods

Fetal karyotyping in 76 cases of fetal loss diagnosed by ultrasonographic visualization between 8 and 18 weeks' gestation was attempted between January 1987 and September 1989. A total of 33 skin biopsy specimens were obtained, 19 from previously expelled spontaneous abortions and 14 from fetal tissues obtained at the time of evacuation of intrauterine fetal deaths. Thirty-six specimens contained products of conception from which placenta and fetal membranes were cultured. All biopsy and products of conception specimens were placed into culture media immediately. All specimens from spontaneous abortion were obtained within 1 hour after delivery, inasmuch as most occurred on route to or in the emergency room. Seven amniocentesis procedures were done at the time of diagnosis of intrauterine fetal death.

From August 1988 to September 1989, 62 patients who had been referred to the Division of Reproductive Genetics at Hutzel Hospital were found to have intrauterine fetal death during detailed ultrasonographic examination before planned chorionic villus sampling. All patients with intrauterine fetal deaths were offered transcervical chorionic villus sampling on an experimental basis to determine whether a chromosomal cause could account for the fetal death. Of the 62 patients offered chorionic villus sampling on this basis, 23 (37.1%) chose to have the chorionic villus sampling performed. All attempts to obtain villi were successful by the transcervical approach, and yielded specimens ranging in size from 0.5 to 50.0 mg.

Specimens were processed by either a direct method or a long-term culture method involving mincing the villi or tissue specimen and culturing in an open system with Chang medium (#T100-058, Irvine Scientific, Santa Ana, Calif.) in T-25 tissue culture flasks (#25100, Corning Glass Works, Corning, N.Y.). All specimens were carefully examined and cleaned under a dissecting microscope before culturing to minimize the risk of maternal cell contamination. The long-term explants were then grown out in monolayer and harvested in suspension after trypsinization. Slides were made at room temperature immediately from cells pelleted and resuspended in 3 : 1 methanol/acetic acid solution. Twenty cells were then analyzed and 5 karyotyped after QFQ and GTG banding. If the sample size was >5 mg, then culturing and a direct method for analysis of mitotic figures were used. The direct method was undertaken on the basis of a modification of Simoni et al.[3] that uses 1% sodium citrate as the hypotonic, an open system with Chang medium, and a 45% to 50% acetic acid solution for cell dispersion. Slides were all prepared with a gravity flow method as described by Bhatia et al.[4] No inconsistencies were noted between results obtained by the short- or long-term methods, and karyotypes reported herein reflect long-term culture results.

Results

Of the 19 skin biopsy specimens from spontaneous abortions, 12 (63.2%) failed to grow. The exact time between delivery and placement in culture was not available from records; therefore the relationship between this variable and success in culturing could not be evaluated. Any specimen obtained more than 1 hour after expulsion was not included in this data. Seven successfully resulted in karyotypes of which four (57.1%) were normal and three (42.9%) were abnormal (69,XXY; 47,XY,+21; 47,XY,+21). In the 14 skin biopsy specimens obtained after evacuation of intrauterine fetal deaths, 12 failed to give results (95.7%) and the remaining two successfully karyotyped were abnormal (45,X/47,XX+21; 46,XX,+t21/21) (Table II).

Cultures from products of conception were more successful; only 13 (36.1%) failed to give results. Of the remaining successfully karyotyped specimens 18 (78.3%) had normal chromosomal complements, whereas five (21.7%) were abnormal (47,XXY; trisomy 9, 13, 16, 21).

Postmortem amniocentesis and postmorten chorionic villus sampling were both found to be technically feasible. The seven amniocentesis cultures resulted in

POC, Products of conception (includes all skin biopsy specimens).
*Includes amniocentesis results.

four (57.2%) growth failures, two (66.7%) normal karyotypes, and one (33.3%) abnormal 45,X karyotype. All 23 chorionic villus sampling specimens were successfully karyotyped, and 22/23 (95.7%) were abnormal. Abnormalities included one 69,XXX; one 69,XXY; three 45,X; one 49,XX,+18,+21,+22; one 46,XX,t(13q14q),+17; and trisomies of chromosome 13, 15 (x2), 16 (x3), 18, 20 (x2), 21 (x3), and 22 (x3).

Overall, the rate of successful growth and karyotyping of all embryonic death tissue was 58.6%. A total of 56.9% of cases were chromosomally abnormal with 71% trisomies, 12.9% 45,X, 9.6% triploidy, 3.2% mosaics, and 3.2% with multiple trisomies. The remaining 43.1% of cases had normal karyotypes. The mean maternal ages for cases with a normal karyotype with the use of the combined data were 29.25 years old, and 36.67 years old for the abnormal karyotype group ($p = 0.0018$) (Table III).

In all cases of skin specimens and products of conception after uterine evacuation for missed abortion, the clinical history was that of growth retardation that led to further evaluation. No histories for recurrent spontaneous miscarriage or fetal losses were found. The mean maternal age of those cases with normal karyotypes in the skin biopsy specimen and products of conception group was 29.33 years, whereas that for the abnormal karyotype group was 33.71 years (p = NS). Unfortunately, in most of these cases the gestational age was not listed, but the range for those in which gestational age was given ranged from 16 to 20 weeks. In the amniocentesis group the maternal ages for those with normal karyotypes were 30 and 21 years old at gestational ages of 19 and 16 weeks, respectively. The abnormal karyotype was from a 30-year-old woman at gestational week 14.

Successful growth and karyotyping of chorionic villus sampling intrauterine fetal deaths was 100%, of which 95.7% had abnormal chromosomal complements

*Mean maternal age = 37.87 ± 3.38 years.
†Mean gestational age = 10.52 ± 1.76 weeks.

(Table IV). The rate of trisomy was 69.56%, 45,X 13.0%, triploidy 8.7%, multiple trisomies 4.3%, and there were no mosaics detected. The most prevalent trisomies were of chromosome 16, 21, and 22 (13.0% overall, 18.8% of chorionic villus sampling trisomies), followed by chromosome 15 and 20 (8.7% overall, 12.5% of chorionic villus sampling trisomies). The single normal result came from a 36-year-old woman at 11 weeks' gestation. The mean maternal age for the abnormal chorionic villus sampling group was 37.87 years and mean gestational age was 10.52 weeks.

The maternal ages of all patients in the skin biopsy specimen and products of conception group were significantly younger than all patients in the chorionic villus sampling group ($p < 0.001$). When the maternal ages were compared for only those with *abnormal* karyotypes in these groups, the skin biopsy specimen–products of conception group was again significantly younger ($p = 0.0214$). The maternal ages of *all* patients with normal karyotypes (29.25 years) were also found to be younger when compared with all patients with abnormal karyotypes (36.67 years, $p = 0.0018$).

Comment

The high incidence of human fetal wastage is a challenging and complex problem. With statistical modeling, Roberts and Lowe[5] postulated a 78% loss rate of all human conceptions, most occurring even before the first missed menstrual period. With radioimmunoassay techniques for quantitative levels of β-subunit human chorionic gonadotropin, Edmonds et al.[6] followed up 118 pregnancies diagnosed on a biochemical basis prospectively and found 67 had elevated human chorionic gonadotropin levels without clinically obvious pregnancy; six of the remaining 61 pregnant women had clinical abortions, for a postimplantation loss rate of 62%. In a study of 34 early fertilized ova from 1 to 17 days, Hertig and Rock[7] found 13 had major abnormalities. In an earlier study, Hertig and Sheldon[8] in a morphometric study of 1000 spontaneous abortions found 75% to have major malformations. Other pathologic studies on abortuses by Mikano[9] and by Miller and Poland[10] supported Hertig's findings and showed the frequency of abnormalities was related to developmental stage. In these studies, 90% to 100% of specimens showed malformations if pregnancy losses were within 4 weeks after fertilization, and the frequency decreased when embryonic death occurred later in gestation.

Such information encouraged the search for genetic causes of pregnancy loss. Kajii et al.[11] studying elective terminations of pregnancy found a 4.5% incidence of chromosome abnormality in 469 successfully analyzed abortuses at 4 to 9 weeks' gestation. Yamamoto and Watanabe[12] found a 6.4% incidence of chromosome abnormalities in 1250 abortuses at 3 to 10 weeks' gestation. They further noted that the percentage was higher the earlier the developmental age of the embryo (9.3% at 3 to 4 weeks, 5.4% at 9 to 10 weeks). Warburton[13] noted that about 50% of chromosomally abnormal fetuses are lost between 8 to 15 weeks' gestation, about 24% in the period 16 to 19 weeks, and about 12% of abnormal fetuses are subsequently lost after 20 weeks.

In 62 patients scheduled to undergo routine prenatal testing, an intrauterine fetal death was diagnosed at the time of routine pretesting ultrasonographic examination. In the 23 patients who elected to undergo chorionic villus sampling, the villi were easily obtained by transvaginal approach, readily grew in culture, and were easily karyotyped. No maternal medical complications occurred as a result of this procedure. Karyotype results were available in 4 to 7 days for chorionic villus sampling specimens in contrast with the usual 2 to 3 weeks for skin, amniocentesis, or products of conception results.

Only one of the 23 specimens gave a normal chromosomal karyotype. There are several explanations for this, with differences in maternal age most siginficant. When *all* skin specimens and products of conception cases are compared with *all* chorionic villus sampling cases, the differences in maternal ages were signifi-

cant (skin–products of conception mean maternal age = 31.25 ± 4.71 years; chorionic villus sampling = 37.79 ± 3.38, $p = 0.0018$). When these data were corrected only for those with *abnormal* karyotypes (skin–products of conception = 33.71 ± 4.54; chorionic villus sampling = 37.87 ± 3.43, $p = 0.0214$), the results were again found to be statistically significant. If the maternal ages of *all* cases with abnormal karyotypes are compared with *all* those with normal karyotypes, the difference is again significant (abnormal = 36.76 ± 4.24 years, normal = 29.25 ± 4.75 years, $p = 0.0018$).

These findings are not unexpected on the basis of the increase in incidence of aneuploidy with advancing maternal age. In fact, 63.6% of the chorionic villus sampling specimens were trisomies. The most common trisomies were in agreement with Warburton's[13] findings in which trisomy 16 was most prevalent, followed by trisomy 21 and 22 (each representing 13% of chorionic villus sampling abnormal karyotypes), followed by trisomy 15 and 20 (8.7%) and then by 13, 17, 18 (4.3%). The 45,X complements were found in 13.6% and triploidy in 8.7%. Reportedly, 45,X is one of the most frequent chromosomal abnormalities found in early pregnancies, and yet only 13.6% of our chorionic villus sampling abnormal karyotypes had this chromosomal complement. Our data agree with other studies that have likewise found a negative association between incidence of 45,X karyotype and advancing maternal age.

Another possible explanation to the high incidence of abnormal chorionic villus sampling karyotypes could be the age at diagnosis. Fetal skin and products of conception specimens generally came from gestations of 14 to 18 weeks, whereas the chorionic villus sampling specimens were obtained at 9 to 11 weeks' gestation (mean = 10.52 ± 1.76 weeks). As noted earlier, the earlier a loss occurs in gestation, the greater the likelihood of an abnormal karyotype.

Last, chromosomal mosaicism might play a role in length of survival of pregnancies. Trophoblastic mosaicism is not uncommon in chorionic villus sampling specimens, but the absence of such in our cases was somewhat a surprise. It has been suggested recently[15] that survivability of anomalous gestations may depend on the presence of mosaicism in the extraembryonic compartment. In a study of trisomy 18 gestations, they suggest that cases that had a large or totally normal diploid component to the extraembryonic compartment might be advantaged, survive longer into gestation, and possibly represent the selective subset of anomalous pregnancies that survive to term. This concept might help explain the higher percentage of normal karyotypes when amnion or trophoblast was sent from intrauterine fetal deaths diagnosed and evacuated or miscarried later in gestation (as in our products of conception data). It may also determine when pregnancy loss occurs, and undoubtedly reflects the impact of each chromosomal abnormality on the ongoing development and differentiation of that particular gestation. This is likely why some chromosome anomalies are never seen in recognized pregnancies, and probably leads to developmental arrest very early in pregnancy. Those chromosome abnormalities (i.e., trisomy 16, 21, and 22), which occur more frequently in recognized pregnancy loss, probably represent a lesser impact on genomically directed embryogenesis and development, allowing more advanced gestational ages to be achieved. We believe that chorionic villus sampling done at the time of diagnosis of an intrauterine fetal death offers the greatest chance of obtaining a karyotype of that gestation. If such an approach is not possible, then a specimen that comprises chorionic villi and adjacent membranes (chorion frondosum) obtained temporally as close as possible to the time of diagnosis may represent a reasonable alternative.

Detection of congenital toxoplasmosis by chorionic villus sampling and early amniocentesis

Walter Foulon, MD,[a] Anne Naessens, MD,[b] Luc de Catte, MD,[a] and Jean-Jacques Amy, MD[a]

Brussels, Belgium

We describe a strategy used in this case to detect congenital toxoplasmosis early in pregnancy. Combination of chorionic villus sampling and early amniocentesis with an in vitro cell culture technique makes prenatal diagnosis of congenital toxoplasmosis possible from the end of the first trimester of pregnancy. (Am J Obstet Gynecol 1990;163:1511-3.)

Key words: Congenital toxoplasmosis, early prenatal diagnosis

Recently the use of cordocentesis for detection of congenital toxoplasmosis in the second trimester of pregnancy[1] was described. Diagnosis of congenital toxoplasmosis is made on the basis of the presence of specific immunoglobulin M (IgM) antibodies and the isolation of the parasite by means of mouse inoculation. Moreover, elevated liver enzymes, low platelet counts, and elevated eosinophils in fetal blood are aspecific markers indicative of fetal infection. Although the procedure of fetal blood sampling is relatively safe it can only be offered from week 19 onward. When seroconversion occurs early in pregnancy or in cases of high initial antibody level in the first trimester of pregnancy one must wait until the moment of fetal blood sampling to know the results of the aspecific indexes of congenital toxoplasmosis. The results of the mouse inoculation test are only available after 4 to 5 weeks. Therefore it seems important to develop an earlier and accurate prenatal diagnosis to reduce the anxiety inherent to the long period of waiting. Moreover, early detection enables termination of the pregnancy or the start of treatment with pyrimethamine and sulfadiazine in cases of proved congenital toxoplasmosis at a much earlier stage.

Case report

A 26-year-old woman was initially seen at 8 weeks' gestation. During routine serologic screening high levels of antibodies against *Toxoplasma gondii* were found. The titer of the Sabin-Feldman dye test was 1/4000, that of the complement fixation test was 1/16, and that of the specific IgM was 1/80. Ultrasonographic examination showed a conceptus with a heart beat and a crown-rump length of 18 mm. The patient was informed of the risk of giving birth to a congenitally infected infant and consented to a prenatal diagnosis at 19 weeks' gestation. Treatment with spiramycin (Rovamycine, Rhône-Poulenc, Paris) 3 gm daily was started from week 9 onward.

A second ultrasonographic scan at 14 weeks' gestation revealed the fetus had died. Before terminating the pregnancy a transabdominal chorionic villus sampling was performed. Ten milligrams of pure placental tissue was aspirated. Amniotic fluid samples were taken immediately thereafter. The chorionic tissue and 3 ml amniotic fluid were used for in vitro culture of *Toxoplasma gondii* on fibroblasts.[2] A second aliquot of 3 ml of amniotic fluid was inoculated into mice and the remaining 20 ml was cultured for determination of the fetal karyotype. The pregnancy was terminated by extraamniotic administration of prostaglandin. The patient expelled a dead fetus without signs of malformation. Fragments of placenta, fetal brain, liver, and lung were processed for detection of toxoplasma by tissue culture method[2] and by means of animal inoculation.

Toxoplasma gondii was identified by tissue culture in the chorionic villus sample (Fig. 1), the placenta, fetal brain, liver, lung, and amniotic fluid after 5 days. The parasite was also isolated after 5 weeks from mice inoculated with amniotic fluid, placenta, fetal brain, and lung. Mouse inoculation of fetal liver remained negative. A chorionic villus sample was not available for mouse inoculation. Histologic examination showed toxoplasma cysts in the fetal brain and placenta. The fetal karyotype was found to be 46,XY and normal.

Comment

An infection with *Toxoplasma gondii* during pregnancy may result in congenital disease. Approximately

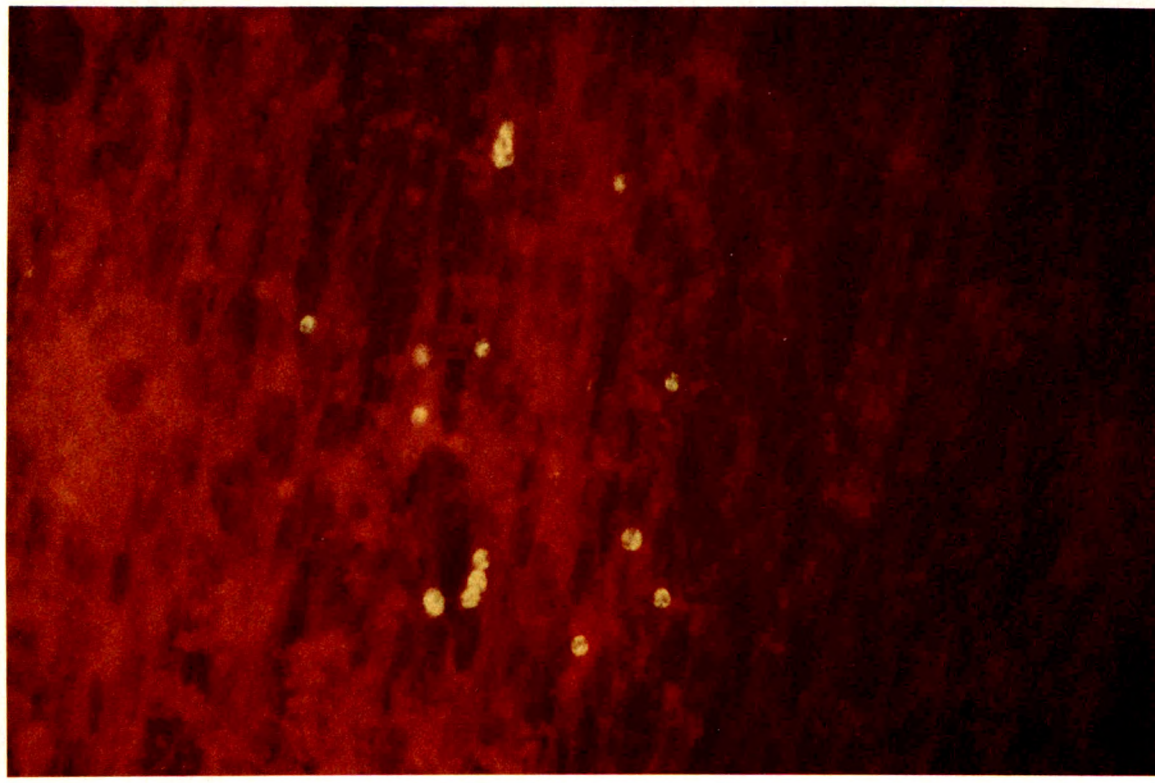

Fig. 1. In vitro cell culture of *Toxoplasma gondii*: Microscopic view of parasite after coloration with monoclonal antibody.

20% of actively infected women before 20 weeks' gestation transmit the parasite to their fetus.[1] Prenatal investigation should be limited to patients in whom seroconversion occurs during pregnancy or in women with high initial antibody levels suggestive of recent toxoplasmosis. Presence of IgM antibodies is not necessarily indicative of recent maternal infection. IgM activity can occasionally persist for some years after a toxoplasma infection or nonspecific reactions may occur. Moreover, some patients may exhibit naturally occurring IgM antibodies. Therefore one must be familiar with the interpretation of the toxoplasma serology in selection of a population at risk of having a congenitally infected fetus.

Prenatal diagnosis of congenital toxoplasmosis by means of cordocentesis is an important step forward in the management of toxoplasma infection during pregnancy. Nevertheless interpretation of the nonspecific tests is not always easy because of their low positive predictive value.[1] Specific signs of congenital toxoplasmosis, namely IgM antibodies, are found in only 21% of affected fetuses[1] and the result of the inoculation of amniotic fluid and fetal blood into mice takes 4 or 5 weeks. This means that the definitive result may not be known until 25 weeks' gestation.

The case we described illustrates that chorionic tissue culture and small amniotic fluid samples taken early in gestation can be used for the detection of congenital toxoplasmosis. Small placental biopsy specimens (10 mg of chorionic tissue) and 3 ml of amniotic fluid are apparently sufficient to detect the parasite in utero. Although a positive placenta culture is not always associated with fetal infection there is a close correlation between positive isolations and congenital infection. The positive predictive value of a positive placenta culture is at least 95%.[3] Combination of chorionic villus sampling and early amniocentesis with an in vitro cell culture technique makes prenatal detection of congenital toxoplasmosis theoretically possible at the end of the first trimester of pregnancy. It must be said that in this case the toxoplasma infection was overwhelming, leading to fetal death. It remains to be proved that chorionic villus sampling and early amniocentesis are as reliable as cordocentesis in the detection of congenital toxoplasmosis. Therefore chorionic villus sampling and early amniocentesis should not replace cordocentesis but rather should be used in association with cordocentesis until more is known about the sensitivity and specificity of diagnostic methods that use these techniques.

The "stuck twin" phenomenon: Ultrasonographic findings, pregnancy outcome, and management with serial amniocenteses

Barry S. Mahony, MD, Charles N. Petty, MD, David A. Nyberg, MD, David A. Luthy, MD, Durlin E. Hickok, MD, and Jack H. Hirsch, MD

Seattle, Washington

Thirteen consecutive twin pregnancies affected by the "stuck twin" phenomenon were reviewed to determine the potential benefit of serial amniocenteses. The fetal survival rate for the eight pregnancies that underwent serial amniocenteses was 69% (11 of 16 fetuses). This is significantly improved compared with a fetal survival rate of 20% among the five preceding pregnancies managed without serial amniocenteses at the same institution ($p = 0.01$). It is also markedly improved compared with a combined fetal survival rate of 16% among 48 previously reported pregnancies with the stuck twin phenomenon managed without serial amniocenteses ($p < 0.0001$). Survival correlated with the absence of concomitant pregnancy complications (i.e., maternal hypertension or intractable labor) and with the absence of severe fetal structural abnormalities. Procedural complications occurred in three of eight pregnancies (37.5%) managed with serial amniocenteses and was attributed as a cause of fetal death in one case. Two of 11 survivors (18%) had complications after serial amniocenteses including brain infarction and renal tubular necrosis. Serial amniocenteses may significantly improve the survival rate of twin gestations affected by the stuck twin phenomenon but may be associated with complications among survivors. (Am J Obstet Gynecol 1990;163:1513-22.)

Key words: Twins, stuck twins, polyhydramnios, oligohydramnios, serial amniocenteses

The "stuck twin" phenomenon has been described as a diamniotic pregnancy in which one fetus resides against the uterine wall in a severely oligohydramniotic sac and the co-twin is in a severely polyhydramniotic sac.[1] It complicates up to 8% of twin pregnancies and 35% of monochorionic diamnionic gestations, although it can also occur in dichorionic and even dizygotic pregnancies.[2-4] Some, perhaps most, cases appear to result from the twin transfusion syndrome, but this is not universally present in the stuck twin phenomenon. The severe disparity of amniotic fluid volume signals a dismal prognosis for both twins with most reports indicating a survival rate of <20%.[1, 3, 5-7] Premature labor develops in almost all cases, probably secondary to uterine distension.[3]

The extremely high mortality rate for these fetuses has stimulated a variety of proposed therapies including selective feticide,[2, 8] hysterotomy for umbilical cord ligation of one twin,[9] bloodletting from a placental vessel,[10] laser coagulation of placental anastomotic vessels, and serial amniocenteses.[2-4, 10-21] However, no comparison studies have been reported to indicate the utility of these management options.

This article describes our experience with regard to serial therapeutic amniocenteses in eight consecutive pregnancies affected by the stuck twin phenomenon and compares the fetal survival rate in these eight pregnancies with the fetal survival rate of the previous five affected pregnancies managed at our institution without serial amniocenteses. These results are also compared with prior reports of the stuck twin phenomenon managed with or without serial amniocenteses.

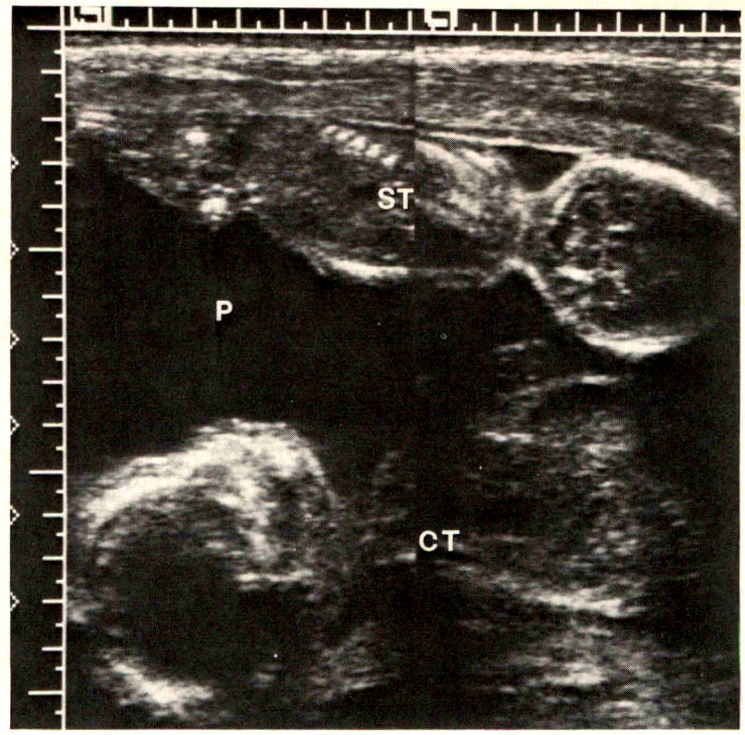

Fig. 1. Dual-image longitudinal ultrasonogram at 19.5 weeks' gestation shows stuck twin adjacent to anterior uterine wall (case 7). Although amnion separating the two fetuses is not apparent on this scan, its presence adjacent to stuck twin is inferred by relative fixation of this twin in nondependent position. Co-twin is in polyhydramniotic sac (additional scans showed a 13 cm vertical pocket of amniotic fluid). *ST*, Stuck twin; *P*, polyhydramnios; *CT*, co-twin in polyhydramniotic cavity.

Material and methods

Seventeen pregnancies with the stuck twin phenomenon were evaluated at this institution between January 1986 and June 1989. Four of these underwent elective second-trimester termination of pregnancy. The remaining 13 pregnancies were managed at this institution and form the basis for this report. In each case, tocolysis was provided as necessary with indomethacin, magnesium sulfate, or ritodrine. Patients were managed on an inpatient basis for preterm labor but were otherwise managed as outpatients. From 1986 through 1987 five of the pregnancies were managed without serial amniocenteses. The subsequent eight pregnancies from January 1988 through June 1989 were managed with serial amniocenteses.

In each case, one twin (the stuck twin) remained relatively fixed in position adjacent to the uterine wall even with changes in maternal position (Fig. 1). Small portions of the thin separating membrane were visible adjacent to the fetus, indicating that the fetus was in a severely oligohydramniotic sac of a diamniotic pregnancy (Fig. 2). The co-twin was in a moderately-to-severely polyhydramniotic sac in each case. We defined moderate-to-severe polyhydramnios as when the largest vertical pocket of amniotic fluid measured >12 cm by ultrasonography.[22] No structural abnormalities were evident on the initial ultrasonographic examination of each of the stuck twins, but two of the polyhydramniotic twins had sonographically detectable structural abnormalities (one case of esophageal atresia and one case of congenital heart disease).

Among pregnancies managed with serial amniocenteses, the amniocenteses were begun at the time of the initial diagnosis after detailed counseling regarding options and potential complications. Amniotic fluid was removed from the polyhydramniotic sac over a period of 45 to 90 minutes under continual ultrasonographic guidance with a 21 or 22 gm Hakko needle attached to a collecting tube. Fluid was removed until the volume of fluid in the polyhydramniotic sac was judged to be normal by ultrasonography (largest vertical pocket of amniotic fluid <7 cm).[22] After the initial amniocentesis was performed, this procedure was repeated when the ultrasonogram showed that the amniotic fluid had reaccumulated to moderate-to-severe levels of polyhydramnios.

We compared the fetal survival rate for the eight pregnancies in this series managed with serial amniocenteses with the fetal survival rate of the preceding five pregnancies managed at this institution without

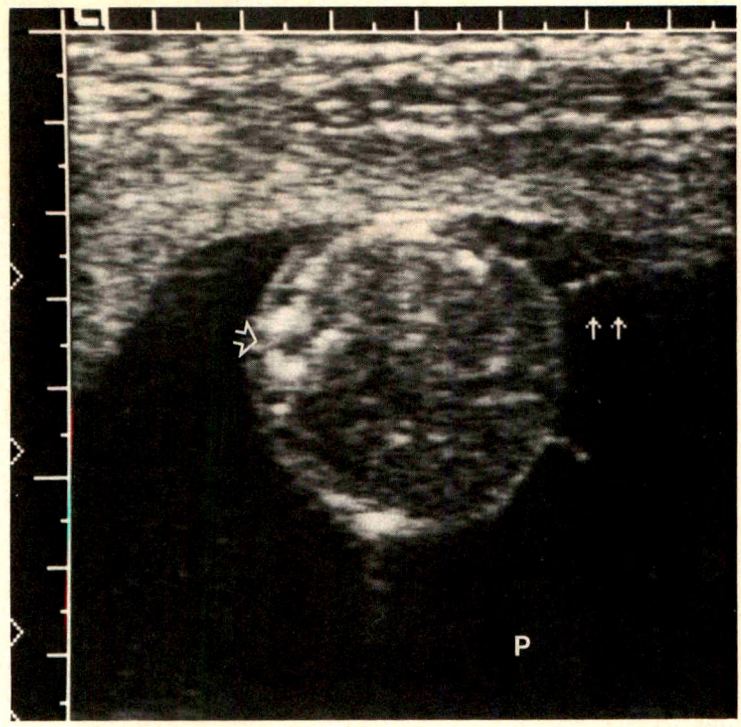

Fig. 2. Cross-section ultrasonogram of abdomen of stuck twin at 16 weeks' gestation shows small portion of amnion as it sweeps off fetus and approaches uterine wall. This indicates that fetus is in severely oligohydramniotic sac (case 8). Additional scans showed co-twin in polyhydramniotic cavity. *Arrows*, Amnion separating the stuck twin from the polyhydramniotic twin; *open arrow*, fetal spine; *P*, polyhydramnios.

serial amniocenteses. We also reviewed previous published reports of twin pregnancies managed with amniocenteses (n = 21) or without amniocenteses (n = 48). Statistical analysis was performed with the Fisher two-tailed exact test.

Results

Table I summarizes the clinical data, medical management, and outcome for the 13 pregnancies with the stuck twin phenomenon managed at this institution since 1986. Two of the 10 (20%) fetuses managed without amniocenteses survived including none of the stuck twins in the oligohydramniotic sac. One survivor occurred in a pregnancy in which its stuck co-twin died at 19 weeks' gestation (case 3). The pregnancy progressed to term without further complications and resulted in a normal neonate who remains well at 30 months. The other survivor in this set of pregnancies was delivered at 27 weeks' gestation because of intractable labor; at 29 months this survivor has chronic obstructive pulmonary disease and hypotonic cerebral palsy related to the extreme prematurity (case 5).

Eleven of the 16 fetuses (69%) managed with serial amniocenteses survived. Fetal death of one twin pair occurred at 24.5 weeks as a result of intractable premature labor and spontaneous rupture of membranes (case 13). Another twin pair died during the neonatal period after a pregnancy complicated by abruptio placentae at 21 weeks, severe maternal hypertension at 31 to 32 weeks, and congenital heart disease of the polyhydramniotic twin (case 12). One fetal death was attributed to a true cord knot that developed after serial amniocenteses (case 11). Two of the 11 (18%) survivors, both in an oligohydramniotic sac, had complications including brain infarction (cases 6 and 7; Fig. 3) and renal tubular necrosis (case 6; Fig. 4). One twin in a polyhydramniotic sac had moderate transient cardiomyopathy that occurred after 5 weeks of severe hydrops fetalis (case 10). Intracranial hemorrhage occurred in two neonates after premature delivery at 30 to 32.5 weeks (cases 7 and 10).

The maternal age and gestational age at the time of initial diagnosis was similar for pregnancies managed with and without serial amniocenteses. However, the gestational age at delivery was greater for the eight pregnancies managed with serial amniocenteses (median, 31 to 32 weeks; mean, 31.4 weeks) than for the preceding five pregnancies managed without amniocenteses (median, 25 weeks; mean, 26.6 weeks). Four of five pregnancies managed without serial amniocen-

teses developed preterm labor and each of these was delivered before 27 weeks; one of these pregnancies progressed to term without tocolysis. Preterm labor developed in five of the eight pregnancies managed with serial amniocenteses and one pregnancy progressed to term without tocolysis.

Table II shows the prenatal data regarding the eight pregnancies managed with serial amniocenteses. The reaccumulation of amniotic fluid did not follow a discernable pattern and the intervals between amniocenteses varied markedly from case to case as well as within individual pregnancies. Procedural complications related to amniocenteses occurred in three of eight (37%) pregnancies and three of 28 (11%) serial amniocenteses. They included chorioamniotic separation (case 7), abruptio placentae (case 12), and rupture of the amnion (case 11). Rupture of the amnion with a subsequent true cord knot was attributed as a cause of one fetal death (case 11).

The fetal survival rate of 69% for the eight pregnancies managed with serial amniocenteses is significantly improved compared with a fetal survival rate of 20% for the five prior affected pregnancies managed without serial amniocenteses at this institution ($p = 0.01$). It is also markedly improved compared with the combined fetal survival rate of 15.6% in 48 previously reported affected pregnancies not managed with serial amniocentesis ($p < 0.0001$).[1, 3, 5-7, 23]

The fetal survival rate for the current series of pregnancies managed with serial amniocenteses is not significantly different from the combined fetal survival rate of 64% from previous reports of 21 twin pregnancies managed with serial amniocenteses ($p > 0.05$; Table III).[2-4, 10-21] Although the lack of prenatal

ultrasonography in early reports precludes confirmation of the stuck co-twin, some authors described an extreme paucity of amniotic fluid in one sac at the time of delivery.[17] One can reasonably presume that many of the early reported cases had the stuck twin phenomenon on the basis of the common occurrence of this phenomenon and the relative rarity of other causes for acute polyhydramnios in twin pregnancies.[24] Combination of the present series with prior reports yields a fetal survival rate of 65.5% among 29 affected pregnancies managed with serial amniocenteses compared with a significantly lower fetal survival rate of 15.6% for 48 affected pregnancies not managed with serial amniocenteses ($p < 0.00001$).

Comment

Marked disparity of amniotic fluid volume that arises acutely in a diamniotic twin pregnancy between approximately 18 and 30 menstrual weeks commonly indicates the stuck twin phenomenon.[1-3] The precise cause of the markedly disparate amniotic fluid volumes in the stuck twin phenomenon remains speculative. It undoubtedly results from the twin transfusion syndrome in some cases, as shown by significant disparity in twin size and by postnatal documentation of placental anastomoses.[23, 25-28] However, other causes must also be operative because the stuck twin phenomenon can occur in dichorionic and even dyzygotic pregnancies.[2-4] In addition, fetal hematocrit levels and umbilical arterial Doppler interrogation often yield variable and confusing findings that do not differentiate donor from recipient twin,[6, 11, 29, 30] and most twins with disparate hemoglobin levels (>5 mg/dl) and disparate birth weights (>20%) do not have the twin transfusion syndrome.[31] Furthermore, in some pregnancies affected by the stuck twin phenomenon either twin may have hydrops, but in other affected pregnancies the polyhydramniotic twin often lacks manifestions of hydrops and the stuck twin lacks evidence of placental insufficiency.

We suggest that diverse causes may initially produce polyhydramnios in one of the sacs of a diamniotic preg-

nancy and eventually result in the stuck twin phenomenon. Case 9, in which the small polyhydramniotic twin had a tracheoesophageal fistula and the stuck twin was structurally normal, represents a relatively unusual cause for the stuck twin phenomenon but exemplifies the effect of the polyhydramnios on the co-twin. The cause of the initial increase in fluid within one amniotic cavity remains unexplained by this hypothesis in cases without structural cause for polyhydramnios. However, once present it may result in increased atriopeptin secretion and cause a feedback mechanism, producing increased urine production and worsening polyhydramnios of the twin in the polyhydramniotic sac.[32-34]

Combined experience from various reports indicates that both twins are structurally normal in approximately 95% of pregnancies affected by the stuck twin phenomenon.[1-3, 5-8, 10, 23, 35] Although neither fetus usually has an identifiable anomaly, the marked disparity of amniotic fluid volume may result from anomalies that lead to polyhydramnios for one twin (including neural tube defect, upper gastrointestinal obstruction, congenital heart disease) or oligohydramnios for the other twin (ruptured amnion, urinary tract anomalies, asymmetric growth retardation).[36] In the current series, two of 13 (15%) affected pregnancies had fetal structural anomalies detected with prenatal ultrasonography, and both anomalous fetuses were in the polyhydramniotic sac. Therefore detection of the stuck twin phenomenon warrants a careful fetal survey of both twins.

Whatever the underlying pathogenesis for the stuck twin phenomenon, it carries an extremely high natural fetal mortality rate of >80%. This high mortality rate has prompted a variety of other proposed prenatal therapies in addition to serial amniocenteses. Selective feticide of the stuck twin was performed in two cases with one case resulting in birth of a normal co-twin. The other case resulted in death of the co-twin.[2, 8] However, the potential for embolism from the dead or dying twin to the live twin via placental anastomoses, as well as the ethical issues associated with selective feticide, limits the utility of this mode of therapy for stuck twins. Umbilical cord ligation has been attempted, although it has not yet been succcessful.[9] Since initially reported by Rivett in 1933, therapeutic amniocenteses have been used occasionally to treat acute polyhydramnios in twin pregnancies.[2-4, 10-21]

Our experience, supported by the composite literature, suggests that serial amniocenteses may provide an effective means of managing pregnancies with the stuck twin phenomenon. The survival rate for affected twin pregnancies at our institution improved significantly

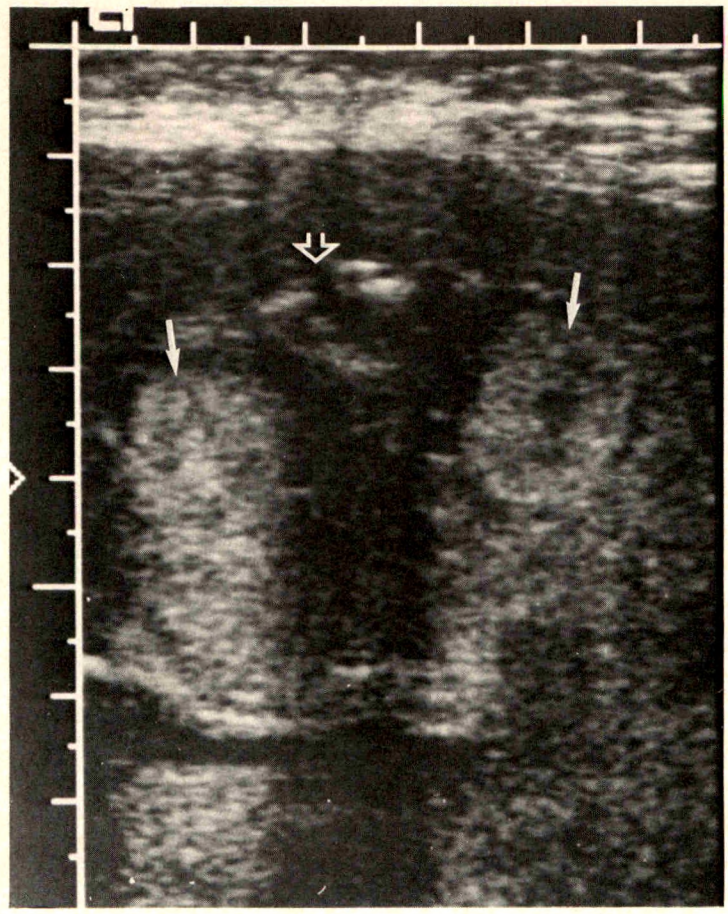

Fig. 4. Transverse ultrasonogram of stuck twin's kidneys at 24.5 weeks' gestation after removal of 5.5 liters of amniotic fluid from polyhydramniotic sac of co-twin, shows kidneys to have abnormally increased cortical echogenicity. This child has chronic renal failure with a stable creatinine value of 2 mg/dl at 15 months (case 6). *Arrows*, Echogenic kidneys; *open arrow*, spine.

from 20% to 69% with the introduction of serial amniocentesis. The survival rate now appears predominantly related to concomitant pregnancy complications or severe fetal malformations. Each of the perinatal deaths in the current series occurred in pregnancies complicated by compromised maternal condition (preeclampsia or intractable premature labor before 27 weeks' gestation), disturbances of the placental membranes (abruptio placentae or rupture of the amnion), or severe fetal structural abnormalities.

Chescheir and Seeds[2] suggest that the success rate of therapeutic amniocenteses correlates inversely with the gestational age at which the polyhydramnios first manifests itself. Among the 14 affected twins in their series, the four that were first seen after 26 weeks' gestation survived, whereas the 10 that were first seen before 26 weeks died. Bebbington et al.[21] also indicate that a more advanced gestational age at the time of clinical presentation and at the time of delivery correlate with a successful outcome. The data from the current series and from the combined experience in the literature, however, indicate a good survival rate even among fetuses that initially are seen as early as 17 weeks' gestation when managed with serial amniocenteses (see Table III). The median gestational age of initial clinical presentation for survivors managed with serial amniocenteses is approximately 24 weeks in the literature and approximately 20 weeks in the current series.

The potential pregnancy complications associated with serial amniocenteses include abruptio placentae amnionitis, rupture of the membranes, inadvertent puncture of the fetus or umbilical cord, onset of labor, and amniotic fluid embolism. Among the 78 serial amniocenteses for the 21 affected pregnancies described in Table III, procedural complications associated with the amniocenteses are described in four (19%) pregnancies. Two of the pregnancies (9.5%) were noted to be in labor a short time later,[2, 11] but this association is

not necessarily causal inasmuch as preterm labor develops in almost all pregnancies affected by the stuck twin phenomenon. One pregnancy (4.8%) developed amnionitis after an amniocentesis.[2] Vetter and Schneider[10] described inadvertent cordocentesis and therapeutic bloodletting in two cases, but one of these cases underwent 16 other amniocenteses without complication. The relatively high procedural complication rate in the current series (three of eight pregnancies; 37.5%) may reflect the role of ultrasonography in the detection of complications that would otherwise remain undetected.

Potential fetal complications encountered among survivors must be weighed against the strong parental desire for continuation of pregnancy. Prior reports rarely mention complications among survivors of serial amniocenteses in twin pregnancies, but most reports provide only minimal postnatal follow-up data. In the currents series, significant fetal morbidity occurred in two fetuses (12.5%) managed with serial amniocenteses (see Figs. 3 and 4). We postulate that the cerebral infarctions may result from transient cerebral hypoperfusion in a destressed fetus or from embolism via the co-twin. Similar postulates might explain the renal cortical necrosis in one twin. Feingold et al.[11] described a case of renal cortical necrosis in a twin after serial amniocenteses of its polyhydramniotic co-twin, and Dimmick et al.[37] reported renal necrosis and cerebral infarction in a growth-retarded twin with the twin transfusion syndrome.

We conclude that serial amniocenteses may significantly improve the survival rate of twin gestations affected by the stuck twin phenomenon, but that other complications may develop in the survivors. Further studies are required to determine the optimal timing and method of amniocenteses to minimize the fetal and procedural complications.

Twin-twin transfusion syndrome

Michael A. Urig, MD,[a] William H. Clewell, MD,[b] and John P. Elliott, MD[b]
Phoenix, Arizona

Twin-twin transfusion syndrome associated with acute polyhydramnios in one sac and severe oligohydramnios in the other, which characteristically is diagnosed between 18 and 28 weeks, is associated with a high mortality rate for the involved twins. Patients who are managed without intervention have essentially 100% perinatal mortality. Nineteen patients with this diagnosis were treated at Good Samaritan Medical Center over a 5-year period. Because of the known perinatal mortality and because of early experiences with the twin-twin transfusion syndrome, we began to actively intervene in such patients with various modes of therapy. As experience was gained, it was found that repeated therapeutic amniocenteses, if performed before severe maternal abdominal distention or labor, appears to be beneficial. (Am J Obstet Gynecol 1990;163:1522-6.)

Key words: Twin-twin transfusion, stuck twin, polyhydramnios

Schatz[1] was the first author to describe the phenomenon of shared circulation between monochorionic twins. Anastomoses have been documented between arteries, veins, and between arteries and veins of each twin, but of greatest importance are the arteriovenous anastomoses that proceed through a placental cotyledonary capillary bed and appear to result in the most dramatic circulatory changes in the twins. Schatz reported that this "third circulation" was usually accompanied by a large arteriovenous anastomosis in the opposite direction to compensate for the inequalities that this third circulation provided. This was the explanation for the finding of some normal outcomes in cases of arteriovenous anastomosis. In the situations in which there was no corresponding large-vessel anastomosis in the opposite direction, it was hypothesized that the "third circulation" predominated and resulted in the transfusion syndrome. When the unequal vascular anastomosis is established the donor twin becomes anemic, hypovolemic, oligohydramnic, and as a result, grows slower than the other twin. The recipient twin becomes polycythemic, hypervolemic, and polyhydramnios develops because of increased urine production to relieve the circulatory overload.[2]

Material and methods

The medical records of Good Samaritan Medical Center were reviewed for the discharge diagnoses of twin pregnancy with associated polyhydramnios. From this group, all 19 patients with twins and associated acute polyhydramnios of one twin and oligohydramnios of the other twin were selected. There was an estimated gestational age difference by ultrasonography of at least 1.5 weeks between the twins in each pair. All diagnoses were made prenatally; the presenting problem was rapid increase in fundal height. In each patient the polyhydramnios was associated with the larger twin, whereas the smaller twin was characteristically "stuck" to the uterine wall, probably as a result of compression from the polyhydramnic twin sac combined with its own oligohydramnios. These characteristics, which are the basis of our diagnosis, are the

same ultrasonographic findings described by other authors.[3-7] These patients represented the worst extreme of the twin-twin transfusion syndrome spectrum with severely discordant growth, acute polyhydramnios, and essentially total oligohydramnios, so that initially the ultrasonographic appearance is of monoamniotic gestation. Patients who did not meet these rigid criteria were not included in this study.

All placentas were found to be monochorionic by gross and microscopic examination. A systemic search for anastomotic vessels was not routinely performed.

Results

Between 1983 and 1987 there were 29,844 deliveries at Good Samaritan Medical Center with 565 sets of twins (incidence of 1:53). There were 19 patients with the diagnosis of twins with acute polyhydramnios and twin-twin transfusion syndrome, an incidence of 1:30 twin pregnancies at our referral center.

The gestational age at the time of diagnosis ranged from 18 to 29 weeks (mean, 22.7 weeks), the majority of pregnancies were in the 21- to 24-week period. The mean gestational age at the time of delivery was 27.3 weeks (excluding elective terminations).

The patients were separated into four groups based on different management philosophy as experience was gained.

Group 1 consisted of five patients early in our experience in whom no intervention was attempted (patients 1 through 5). These patients were seen with the mentioned previously symptoms of rapid uterine distention and preterm labor with cervical change. Historically, twin-twin transfusion syndrome was believed to be associated with essentially 100% mortality at this gestation. Despite tocolysis, all five patients progressed to active labor with rupture of membranes and delivery of nonviable infants (Table I). One patient (no. 4) had intrauterine fetal death of both twins in the course of labor.

Group 2 consisted of patients referred for twin-twin transfusion syndrome in whom preterm labor had already begun. Patients experienced contractions (>two contractions per 10 minutes) and had documented cervical change. Repeated therapeutic amniocenteses were attempted in four patients after they were in preterm labor (patients 6, 7, 8, and 9). It was evident that the removal of amniotic fluid during active labor was not effective in significantly prolonging pregnancy (Table II). Two infants survived (25% survival rate); however these infants were 29 weeks' gestational age at the time of diagnosis.

Group 3 included five patients who initially were seen with severe twin-twin transfusion syndrome with both twins viable, but with a change in intrauterine physiology with the death of one twin (patients 10 through 14). One patient (no. 11) elected termination of the living twin 23 days after the death of the first twin. One patient (no. 14) had the surgical removal of one twin at 21 weeks following three therapeutic amniocenteses.[8] Patient 12 had continued polyhydramnios in the amniotic sac of the recipient twin after death of the donor twin. This patient had therapeutic amniocentesis with removal of 1800 ml of amniotic fluid. The polyhydramnios never reaccumulated and she was delivered at term (Table III). The other three patients did not undergo amniocentesis.

Table I. Cases of twin-twin transfusion syndrome with no intervention

3	22	0	0
4	24	0	0
5	18	0	0
			0/10 (0%)

The four pregnancies that continued (patients 10, 12, 13, and 14) gained an average of 69 days' gestation after diagnosis. Three of the four remaining infants lived. The remaining twin (patient 14) died after birth during operation to correct congenital aortic stenosis after prolongation of pregnancy from 21 to 27 weeks.

Group 4 comprised five patients from our most recent experience in whom aggressive amniocentesis was begun before any signs of preterm labor (patients 15 through 19). Aggressive amniocentesis was defined as repeated amniocenteses that were performed in an attempt to maintain the level of the amount of fluid surrounding the recipient twin at a level as normal as possible. One to five liters of fluid was removed over a 30-minute to 2-hour period. The amount removed was sufficient to maintain a low-normal to normal amount of amniotic fluid in the recipient's sac. Patients received prophylactic tocolysis with intravenous magnesium sulfate during and after therapeutic amniocentesis. In two patients it was found that initial aggressive removal of fluid early in the disease process appeared to stop the transfusion progression (patients 17 and 19). The average number of days gained was 64.2 days (Table IV). Two infants died from severe prematurity after prolongation of pregnancy from 22 to 25 weeks (patient 15), and two infants died of sepsis after prolongation of pregnancy from 21 to 27 weeks (patient 19). There was an overall survival rate of 60% in this group.

Therapeutic amniocentesis before the onset of preterm labor is significantly more effective than amniocentesis after labor has started in prolonging gestation

beyond 27 weeks ($p \leq 0.03$) and beyond 32 weeks ($p \leq 0.01$) (χ^2 analysis). Therapeutic amniocentesis is not significantly different in effect than the death of one twin in prolonging gestation beyond 27 weeks or 32 weeks (χ^2 analysis).

Comment

A review of the literature with regard to the twin-twin transfusion syndrome reveals a wide spectrum of patients labeled with this diagnosis. Because of its relatively infrequent presentation, many of the published accounts are single case reports. Some reports indicate a relatively good prognosis for this syndrome.[9-12]

A continuum of dysfunction clearly exists under the label twin-twin transfusion syndrome. Mild manifestations of this process are probably represented by reports of low mortality and morbidity associated with twins delivered with discordant weights and hemoglobin concentrations.[12-14] One such report[14] detailed only seven sets of twins that were premature of 35 cases reported. Rausen et al.[12] reported a significant incidence of term pregnancies, and many did not have associated polyhydramnios. Patients in these reports seem to represent the benign end of the spectrum of twin-twin transfusion syndrome, which manifests itself later in pregnancy and allows delivery at a later gestational age.

Of greater significance are those patients who are seen with acute polyhydramnios at 18 to 28 weeks, when morbidity and mortality approach 100%. Weir et al.[10] reported eight patients with twin-twin transfusion syndrome and acute polyhydramnios treated expectantly with 100% perinatal mortality. Chescheir and Seeds[7] reported five cases, with 100% mortality in true severe twin-twin transfusion syndrome, and four surviving fetuses in two patients in whom the diagnosis was questionable (one set of dichorionic twins, one male and one female), and one set of twins without polyhydramnios or oligohydramnios. Schneider et al.[15] reported a survival rate of 44% after use of amniocentesis to intervene in nine cases of severe twin-twin transfusion syndrome.

These diverse outcome data are consistent with Schatz's original description of the syndrome. He theorized that many arteriovenous anastomoses were accompanied by reciprocal communications that minimize the discrepancy of blood flow. The patients who are delivered at later gestations probably have such compensatory anastomoses. The infants are born with weight and hemoglobin discrepancies but are not commonly complicated by polyhydramnios/oligohydramnios.

Acute polyhydramnios is probably the most impressive finding in patients who are seen with early severe twin-twin transfusion syndrome, and the polyhydramnios is usually the presenting problem. All patients in our series had acute polyhydramnios. The acute polyhydramnios is usually the cause of preterm labor and preterm rupture of membranes that complicate this problem. All patients in this series had a larger twin with polyhydramnios associated with a smaller twin "stuck" to the uterine wall in an oligohydramnic sac. They were at the severe end of the continuum of twin-twin transfusion syndrome; the mortality in such cases is expected to be 100%.

Amniocentesis has been found to be a safe therapeutic method of relieving maternal symptoms as a result of abdominal distention from polyhydramnios.[11, 15-19] Several authors have suggested that pregnancy can be prolonged in the situation of acute polyhydramnios and twin-twin transfusion syndrome.[11, 15-17, 19] Two groups of patients in our series were treated with aggressive amniocentesis (groups 2 and 4). Traditionally, small amounts of fluid (200 to

500 ml) have been removed during amniocentesis. It is commonly believed that drainage of large amounts of amniotic fluid might cause abruptio placentae or preterm labor. None of the patients in this series from whom large amounts of fluid were removed had evidence of abruptio placentae. In our patients amniocentesis in an actively contracting uterus was not effective in prolonging pregnancy. The only patients who had significant preterm labor during or after amniocentesis were those in group 2 who were already having significant contractions with cervical change at the time of amniocentesis. Caldeyro-Barcia et al.[20] reported that patients at risk for preterm labor who had amniocentesis for polyhydramnios were those with strong uterine contractions at the time of amniocentesis. His review also showed that the incidence of preterm labor in patients with polyhydramnios was much lower if the amniocentesis was performed earlier in pregnancy when uterine contractility is low, and before severe distention. Our experience has been consistent with this finding. If amniocentesis can be performed at the time of diagnosis, and before significant contractions are present, there is a reduced chance of premature labor associated with therapeutic amniocentesis; in this group of five patients (Table IV), 60% survival was noted.

After amniocentesis had been initiated, our goal was to maintain the amniotic fluid volume around both fetuses at a level as close as possible to the normal range. As suggested by Mills,[17] we drained amniotic fluid as often and as rapidly as necessary to maintain the normal amniotic fluid volume in each sac (range, repeat in 1 day to 3 weeks). The largest amount of fluid removed from our group of patients over an 8-week course of therapy was 19 L; 5 L was the largest volume removed at one time. The patients in this series who gained a minimal number of days' gestation were either in preterm labor at the time of the first amniocentesis or were seen with premature rupture of membranes (groups 1 and 2). Chescheir and Seeds[7] did not appreciate significant lengthening of gestation in their three patients who underwent therapeutic amniocentesis. Uterine activity and cervical dilatation were not mentioned and may have been contributing factors. In their series chorioamnionitis developed in one patient after amniocentesis. No patient in our series had signs of chorioamnionitis, and antibiotics were not routinely used prophylactically.

We suggest that amniocentesis be performed for both fetal and maternal reasons. We observed normal fluid volumes around both twins after therapeutic amniocenteses in numerous patients. The only other report of this phenomenon is by Schneider et al.[15] In their study a placental vessel was inadvertently punctured during amniocentesis. Our experience suggests that repeated, aggressive amniocenteses reduce the rate of fluid accumulation in most cases. Only one therapeutic amniocentesis was needed in two cases and in the other three cases the repeated amniocenteses generally occurred after an increasing number of days between amniocenteses. The physiologic reason for this response is uncertain. It is possible that the transfusion syndrome begins at a low level, probably between 16 and 20 weeks. The recipient twin then has an increase in its glomerular filtration as a result of increased renal perfusion. With the accumulation of fluid in the recipient's amniotic sac, the donor twin and its portion of the placenta become compressed and increase the rate of transfusion to the recipient twin. Intravascular hypovolemia in the donor results in decreased renal perfusion and oliguria. It is possible that the relief of pressure exerted by the recipient's polyhydramnios on the donor twin's placental vessels alone is sufficient to partially reverse this phenomenon.

Our experience supports the fact that the intrauterine environment can be normalized if the physiologic characteristics are changed early in the course of this transfusion situation, by therapeutic amniocentesis or the death of one twin. Usually therapeutic amniocentesis should be started in the 16- to 21-week period for best results.

Alternative approaches to the twin-twin transfusion syndrome include fetal surgery or selective in utero termination. These alternatives should be considered only in very severe, early situations, and only after failed attempts at therapeutic amniocentesis.[7, 21] The option of selective in utero termination can lead to

other serious complications involving embolic phenomena and coagulation defects in the remaining twin.[22-24] This is an experimental procedure and is fraught with technical and ethical problems.

The condition of twin-twin transfusion syndrome associated with acute polyhydramnios has a grave prognosis. In most cases, the diagnosis is made at a gestational age when survival for even a normal singleton is doubtful. These fetuses are normal genetically but are subjected to extreme physiologic changes as a result of the abnormal circulatory condition. The goal of therapy should be to prolong the pregnancy to increase the chance of fetal survival.

Of the reports of twin-twin transfusion syndrome in the second trimester when no therapy was instituted, there was essentially 100% perinatal mortality unless one twin died in utero. Twin-twin transfusion syndrome is a rare problem but contributes significantly to perinatal mortality in twins. The survival of such twins can be improved with active early intervention with aggressive therapeutic amniocentesis.

Pregnancy in a patient with treated Wilson's disease: A case report

Patrick Dupont, MD, Olivier Irion, MD, and François Béguin, MD
Geneva, Switzerland

Pregnancy should have a successful outcome in a patient with treated Wilson's disease if complications are excluded before conception. Chelating treatment must be maintained, although there is some concern about its teratogenicity. We describe the course of pregnancy in a patient followed up in our department.
(AM J OBSTET GYNECOL 1990;163:1527-8.)

Key words: Wilson's disease, pregnancy, penicillamine, teratogenicity, trientine

Wilson's disease is an autosomal recessive disorder of copper metabolism characterized by liver cirrhosis and central nervous system dysfunctions. Before the advent of penicillamine, successful pregnancies were rare events. We report one pregnancy followed up in our department and discuss the problems related to this condition and its treatment with regard to pregnancy and the fetus.

Case report

At the age of 21 years, M. K. was admitted to a psychiatric unit for depression. Her history revealed one episode of weakness and abnormal liver function test results at 17 years of age. Two years later she left college because of deteriorating performance. In the following months increasing asthenia, dysarthria, irregular handwriting, difficulty in walking, sialorrhea, and bursts of incoercible laughter developed. Her gynecologic history revealed no menstrual irregularities or miscarriage.

Laboratory tests revealed: thrombocytopenia (78,000/mm^3), slightly elevated liver enzymes, normal serum copper (13 mmol/L), diminished ceruloplasmin (0.13 gm/L, low urine copper excretion (1.1 mmol/day), increased intrahepatic copper concentration (15.8 mmol/gm dry weight), impaired renal functions with glucosuria, phosphaturia, and uricosuria. Wilson's disease was diagnosed. Cerebral computed tomographic scan revealed a discrete bilateral hypodensity affecting the lentiform nuclei and abdominal laparoscopy showed a macronodular liver cirrhosis with hepatosplenomegaly and signs of portal hypertension.

Penicillamine therapy (750 mg/day) and a low copper diet brought rapid clinical improvement. Hepatic function normalized, serum copper level decreased, urinary copper output increased, thrombocytopenia did not improve. Penicillamine was well tolerated and the patient showed no other side effects.

Two years later the patient became pregnant. An abortion was performed.

At age 25 years, when she consulted a new practitioner, the question of motherhood was raised. Data from the medical literature showed that pregnancy in her condition seemed reasonable in an appropriate obstetric setting. Thus she was referred to our department for a thorough evaluation of her condition. Increased urine copper excretion and stable clinical condition proved the patient's compliance to therapy. Liver assessment (ultrasonography, nuclear magnetic resonance, and aminopyrine breathing test) showed hepatosplenomegaly but neither cirrhosis nor hepatic failure. An esophagogastroduodenoscopy revealed nonsymptomatic esophageal varices. With this information pregnancy was deemed reasonable.

Genetic counseling was performed. The risk of a future child inheriting that condition was estimated at 1/200 to 1/400, inasmuch as no other case of Wilson's disease was discovered in the family.

A few months later the woman became pregnant. Penicillamine 750 mg/day was continued. The course of pregnancy was uneventful. Liver function test results were normal and, as expected during pregnancy, serum copper and ceruloplasmin levels increased as did urine copper excretion. Thrombocytopenia remained stable. At the beginning of the third trimester, endoscopy confirmed small esophageal varices. Occult blood tests in stools were negative.

Because of increasing maternal fatigue, birth was induced at 38 weeks' gestation. A girl of 3010 gm was delivered spontaneously. Apgar scores were 9 and 10 at 1 and 5 minutes, respectively, and arterial pH was 7.30. Cord blood showed both normal serum copper (8.3 mmol/L) and ceruloplasmin (0.14 gm/L) in the infant.

The postpartum period was uneventful for both mother and child.

Comment

As is evident from this case and others,[1] pregnancy should have a successful outcome in patients with Wilson's disease provided that complications such as portal hypertension and impending hepatic failure are excluded before conception. Chelating treatment must be continued throughout pregnancy at the optimum dosage to avoid any severe relapse or damage to the fetus.

The teratogenic effects of penicillamine remain controversial. Dose-related teratogenesis has been proved in rats. Birth defects have been reported in four newborns of mothers with penicillamine-treated Wilson's disease: two infants had transient cutis laxa and one also had micrognathia, low-set ears, inguinal hernias, and joint mobility. Other defects possibly not related to penicillamine were reported in two patients: bilateral club feet, cerebral palsy, blindness, arthrogryposis multiplex, hip dislocation, and a marked hydrocephalus with intraventricular hemorrhage.[2]

A safer alternative to penicillamine could be triethylene tetramine dihydrochloride (trientine), a newer chelating agent with efficiency that equals penicillamine. Even though teratogenicity in the rat was described, its use in pregnancy as reported in a small series[3] showed no birth defects or copper depletion in the fetus.

Nature of gonadotropin-releasing hormone self-priming of luteinizing hormone secretion during the normal menstrual cycle

Michael J. Sollenberger, MD, Elisabeth C. Carlsen, MD, Robert A. Booth, Jr., MS, Michael L. Johnson, PhD, Johannes D. Veldhuis, MD, and William S. Evans, MD
Charlottesville, Virginia

To investigate further the nature of the gonadotropin-releasing hormone self-priming effect on luteinizing hormone release, we administered two submaximal doses of gonadotropin-releasing hormone 2 hours apart to women at three stages of the menstrual cycle and analyzed the resultant luteinizing hormone secretory episodes with deconvolution analysis. When the characteristics of the secretory episodes associated with the second gonadotropin-releasing hormone challenge were compared with those associated with the first, both an enhanced maximal secretory rate and mass of luteinizing hormone secreted was demonstrable at each phase of the cycle. No differences in the luteinizing hormone secretory event half-duration were detected when the responses to the first and second gonadotropin-releasing hormone doses were compared. These data confirm the gonadal hormone milieu–associated self-priming effect of gonadotropin-releasing hormone on luteinizing hormone release and indicate that it is the rate with which luteinizing hormone molecules are discharged from the pituitary gland, rather than the duration of the secretory episode itself, that provides for the self-priming effect. (AM J OBSTET GYNECOL 1990;163:1529-34.)

Key words: GnRH self-priming, deconvolution analysis

The ambient gonadal hormone environment modulates gonadotropin-releasing hormone (GnRH)–stimulated luteinizing hormone (LH) secretion both in vivo[1-5] and in vitro.[6] Moreover, under appropriate conditions in humans,[4, 7] in animal models,[3, 5, 8-11] and in vitro,[3, 6, 12-14] repetitive administration of GnRH results in significant potentiation of LH secretion by the anterior pituitary gland. This phenomenon of enhanced pituitary responsiveness associated with multiple GnRH challenges has been referred to as "self-priming" and may represent a primary mechanism subserving the preovulatory LH surge.[3, 6, 8-10, 13]

Despite intensive investigation, the mechanisms that subserve GnRH self-priming remain to be clarified. To date, studies in the human have focused entirely on changes in the circulating concentration of LH after the administration of serial pulses of GnRH. Although of obvious importance with regard to defining the event, these observations have been primarily descriptive in nature and have not provided insight into the determinants of the GnRH-stimulated LH secretory burst. Recently a novel analytic approach known as multiple-parameter deconvolution has been successfully applied to a variety of hormonal secretory profiles.[15] This technique allows for the simultaneous resolution of specific, quantitative features of hormone secretion together with subject-specific metabolic clearance rates. We have used this model in this study to assess LH secretion in response to two submaximal bolus infusions of GnRH administered 2 hours apart in 12 women at three stages of the menstrual cycle. With this design, both the effect of the gonadal hormone milieu on GnRH-stimulated LH secretion (in response to the first bolus of GnRH) and on GnRH self-priming (LH secretion in response to the second versus the first GnRH bolus) could be assessed. Specifically, we tested the hypotheses that the self-priming phenomenon defined previously by changes in serum concentrations of LH may reflect either (1) alterations in one or more attributes encoding for the luteinizing hor-

Table I. Mean (± SEM) serum concentrations of gonadal steroid hormones in normal women at three phases of menstrual cycle*

mone secretory events stimulated by GnRH or (2) alterations in the half-life of secreted hormone.

Material and methods

Subjects and experimental procedures. Twenty-nine young women (mean age, 28 years; range, 18 to 40 years) were studied on one or more occasions at the University of Virginia Clinical Research Center. The study was approved by the Human Investigation Committee of the University of Virginia and each subject provided written consent. All volunteers had a normal history and physical examination and normal serum concentrations of LH, follicle-stimulating hormone, prolactin, thyroxine, thyrotropin, and total testosterone. During the month of study the phase of the menstrual cycle was documented by daily blood samples for measurement of 17β-estradiol, progesterone, and LH. Twelve women were studied in each of three stages of the menstrual cycle including the early follicular phase (days 2 to 4 after beginning of the menses), the late follicular phase (1 to 4 days before the LH surge), and the midluteal phase (5 to 9 days after the LH surge). On the day of study blood samples were obtained from an indwelling heparin cannula at 10-minute intervals from 8 AM to 12 noon. GnRH (10 μg intravenously) was given at 8 AM and 10 AM.

To be included in the analysis, the LH concentration response to the GnRH bolus had to be sufficient to fulfill the following criteria: (1) a peak increase of at least 2 mIU/ml above baseline, (2) a peak response occurring within 20 minutes of GnRH injection, (3) a nonzero decay slope, and (4) 95% of samples available for analysis.

Assays. Serum concentrations of prolactin, thyroxine, thyrotropin, testosterone, estradiol, and progesterone were determined by radioimmunoassay. Progesterone radioimmunoassay was performed with reagents supplied by Diagnostic Products (Los Angeles). Serum LH and follicle-stimulating hormone concentrations were measured with reagents from Clinetics Corp. (Tusten, Calif.). Median intrassay coefficients of variation (calculated from each subject's 145 samples collected over the preceding 24 hours) ranged from 4.6% to 6.2%. All samples from an individual woman were analyzed in duplicate in the same assay.

Deconvolution analysis. Serum hormone concentrations result from the combination of the underlying pituitary secretory events and endogenous (subject-specific) metabolic clearance. Deconvolution analysis allows for the simultaneous determination of the quantitative properties of underlying secretory bursts (characterized by a finite mass, amplitude, and duration) and endogenous clearance kinetics.[15] Endogenous clearance kinetics are related to half-lives by the relationship $MCR = (\ln 2/t_{1/2})/V_d$, where MCR is the metabolic clearance rate and V_d represents the volume of distribution. An LH secretory event is represented algebraically by a gaussian distribution of instantaneous molecular secretory rates that are centered around a particular point in time and dispersed with a finite standard deviation. Multiple-parameter deconvolution procedures were applied separately to the LH data obtained after the administration of each GnRH bolus (8 AM to 10 AM and 10 AM to 12 noon).

Statistical analysis. One-way analysis of variance with Duncan's multiple-range test was used to compare interphase differences in serum concentrations of gonadal steroids. Similar analyses of interphase secretory burst properties and LH half-lives were performed after logarithmic transformation of the data because of departures from normality. Comparisons of these parameters for each GnRH bolus were made by nonparametric methods (Wilcoxon signed-rank test). Correlations between two measures were sought by linear regression analysis of untransformed data. Multiple linear regression using the R^2 maximal improvement criterion was applied to define relationships among three or more variables.

Results

Circulating concentrations of gonadal hormones. The mean serum concentrations of gonadal hormones are summarized in Table I. Serum 17β-estradiol concentrations were similar in the late follicular and midluteal phases and significantly higher than in the early follicular phase. Circulating progesterone concentrations were increased in the midluteal phase, but was indistinguishable in the two follicular phases studied.

Analysis of luteinizing hormone secretion in response to the initial GnRH bolus (GnRH 1). Fig. 1 shows GnRH-stimulated LH concentration time series and the corresponding deconvolution-resolved LH secretory impulses obtained in a representative woman studied at three phases of the menstrual cycle. Visual inspection of these data suggested the presence of cycle-dependent differences in LH secretory event amplitude

Table II. Mean (± SEM) LH secretory burst characteristics during early follicular, late follicular, and midluteal phases of menstrual cycle

GnRH (10 μg intravenously) was given at 0 (GnRH 1) and 2 (GnRH 2) hours.

Duration (in minutes) of the computer-resolved LH secretory burst at half-maximal amplitude.

The volume term (milliliters) represents unit distribution volume. Amplitude is the maximal rate of LH secretion attained in the deconvolution-resolved LH secretory burst.

Entries within each GnRH 1 column identified by different superscripts (*a* and *b*) differ significantly (Duncan's multiple-range test of log transformed values, $p < 0.05$).

*Comparisons of secretory burst properties and LH half-lives (GnRH 1 vs GnRH 2) were made by nonparametric options (Wilcoxon signed-rank test): $p < 0.01$.

†Comparisons of secretory burst properties and LH half-lives (GnRH 1 vs GnRH 2) were made by nonparametric options (Wilcoxon signed-rank test): $0.01 < p < 0.05$.

(maximal secretory rate) and half-duration in response to the first and second challenges with GnRH. Analysis of the deconvolution-resolved secretory event characteristics confirmed this visual impression. Table II summarizes the LH secretory event characteristics inferred in response to the first bolus of GnRH as a function of the phase of the menstrual cycle. Although there was a trend toward a higher maximal LH secretory rate in response to GnRH during the late follicular versus the early follicular phase, a significant difference was not realized ($p = 0.076$). In contrast, the maximal secretory rate during the midluteal phase was significantly greater than that observed in the early follicular ($p = 0.0002$) or late follicular ($p = 0.021$) phases. However, during the late follicular phase the duration of the GnRH-associated LH secretory event was substantially longer than that documented during the early follicular ($p = 0.022$) and midluteal ($p = 0.041$) phases. The mass of LH released in response to GnRH was greater in both the late follicular and midluteal phases of the cycle compared with the early follicular phase ($p = 0.002$ and 0.0001, respectively), but the former two were indistinguishable ($p = 0.376$). Whereas the half-life estimates of LH released during the early follicular and late follicular phases were similar ($p = 0.754$), that of the material secreted in the midluteal phase was significantly shorter ($p = 0.0001$).

Comparison of luteinizing hormone secretory response to GnRH boluses (GnRH 1 vs GnRH 2). Table II also shows the LH secretory event characteristics in response to a second challenge with a submaximal dose of GnRH administered 2 hours after the initial bolus. During the early follicular phase both the maximal rate of LH secretion and the mass of LH released were greater ($p < 0.01$ and $p < 0.05$, respectively) in response to the second versus the first GnRH challenge. However, neither the secretory event duration nor the half-life of hormone secreted differed. The same pattern was evident during the midluteal phase [i.e., a higher maximal secretory rate ($p < 0.05$) and mass ($p < 0.01$)], but indistinguishable duration and half-life of LH were found when the response to the second GnRH bolus was compared with the response to the first. During the late follicular phase, both the maximal secretory rate and mass of hormone secreted were increased in response to the second challenge with GnRH ($p < 0.05$ and $p < 0.01$, respectively). However, during the late follicular phase, and in contrast to the results obtained in the early follicular and midluteal phases, the half-life of secreted LH in response to the second injection of GnRH was significantly ($p < 0.01$) shorter than that released in response to the first dose. No difference in the secretory burst duration was detected.

Correlations among GnRH-stimulated secretory event characteristics and the circulating concentrations of the gonadal hormones. When all women were considered as a group across various stages of the menstrual cycle, multiple stepwise linear regression analysis demonstrated that serum estradiol concentrations were significantly predictive of the mass of LH secreted after the first GnRH injection ($p < 0.0001$ and $R^2 = 0.41$ for mass). Serum estradiol levels also predicted the maximal rate of LH release after the first GnRH pulse ($p = 0.004$). Serum progesterone concentrations predicted the LH half-life ($p < 0.004$) and the half-duration ($p < 0.02$) of the first LH secretory burst.

When individual phases of the menstrual cycle were considered alone, the following findings emerged: (1)

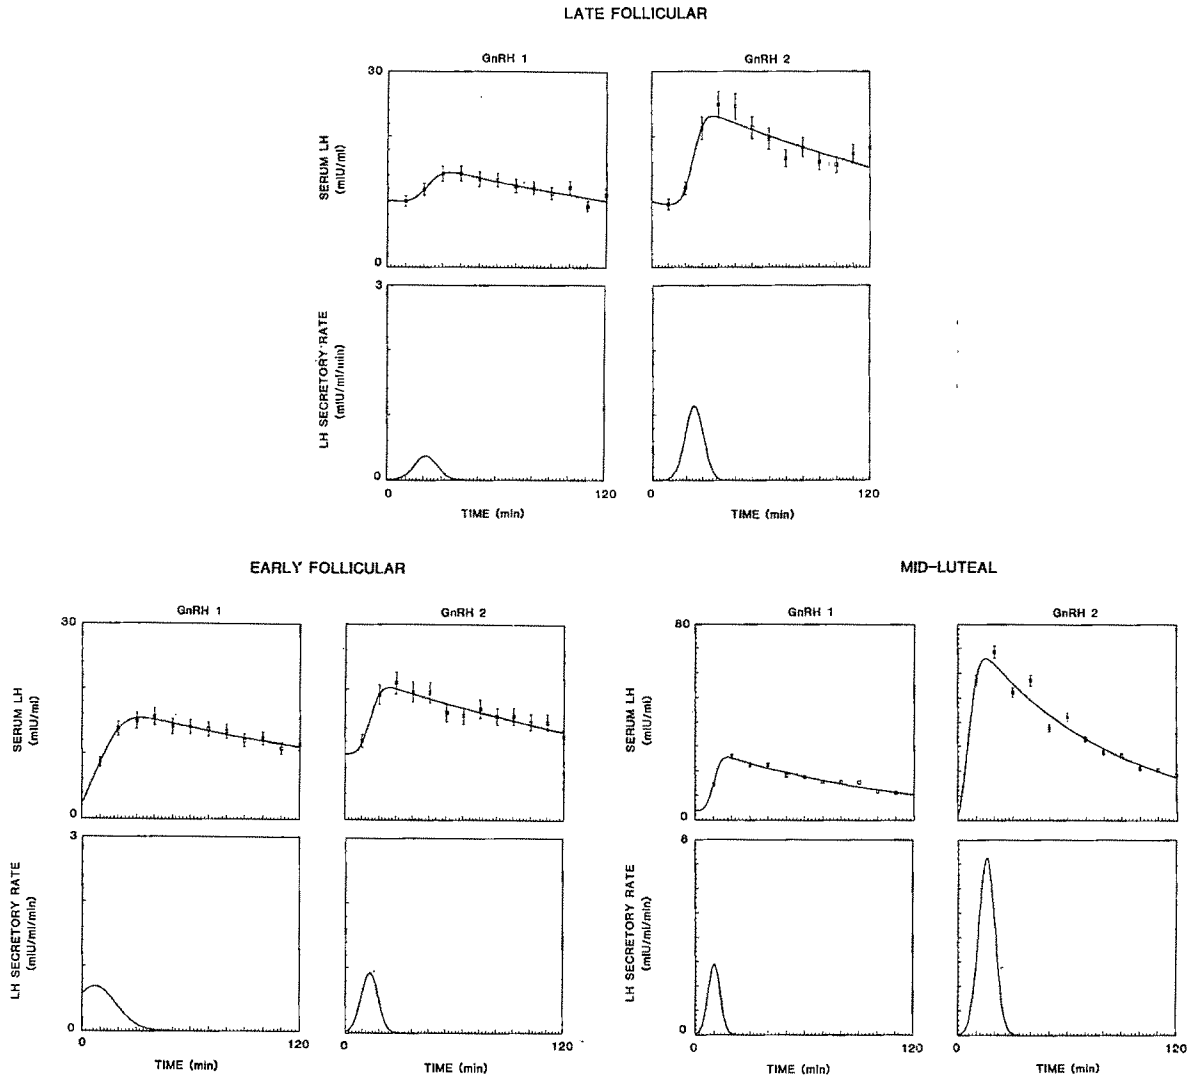

Fig. 1. Illustrative profiles of the deconvolved LH secretory impulses in response to two GnRH challenges (*GnRH 1* and *GnRH 2*) in a representative normal woman. For each phase of the menstrual cycle the *upper panel* depicts measured serum LH concentrations (mean ± SD) and the fitted reconvolution curve *(continuous line)*, which is based on the calculated secretion and clearance parameters. The resolved LH secretory impulses are shown in the *lower panel.*

in the early follicular phase, serum estradiol levels were predictive of both the second luteinizing hormone secretory burst's mass (or its maximal rate) and its half-duration ($p < 0.05, R^2 \geq 0.48$); (2) in the early follicular (but not late follicular) phase, serum progesterone concentrations predicted LH secretory burst mass after the first pulse of GnRH ($p = 0.03$, $R^2 = 0.42$); (3) in the late follicular and midluteal phases, serum estradiol values correlated with the mass and the maximal rate of luteinizing hormone secreted after the first pulse of GnRH ($p < 0.03, R^2 \geq 0.48$); (4) in the midluteal phase, serum 17β-estradiol predicted both the mass of LH secreted and the half-duration of the second LH release episode ($p < 0.03$, $R^2 > 0.63$); and (5) in the midluteal phase, serum progesterone concentrations were significantly predictive of the mass of LH secreted after the second GnRH pulse ($p = 0.008$, $R^2 = 0.56$). Thus, in each of the different phases of the menstrual cycle, serum estradiol concentrations correlated positively and significantly with the mass and maximal rate of LH secretion attained in response to exogenous pulses of GnRH.

Comment

Although the importance of the preovulatory LH surge within the context of normal reproductive function has long been recognized, the cellular events that signal the dramatically increased serum concentrations of LH at midcycle remain incompletely defined. Data obtained in animal models suggest that the secretion of

GnRH into the hypothalamic-hypophysial portal circulation is markedly enhanced coincident with the preovulatory LH surge.[16] However, it is generally accepted that increased GnRH secretion does not solely account for the midcycle LH surge; rather it is thought that the surge reflects a situation in which increased concentrations of GnRH impinge on an anterior pituitary gland that has been rendered considerably more responsive to the releasing hormone just at midcycle. Accordingly, significant investigative interest has focused on the mechanisms subserving this alteration in gonadotroph responsivity.

That GnRH-stimulated LH release is dependent on the gonadal hormone milieu has been documented in a variety of in vivo and in vitro studies.[1-6] Of particular interest are the reports suggesting that, under appropriate conditions, enhanced LH release is observed in response to GnRH after an initial challenge with a "priming" dose of the hypothalamic peptide.[3-6, 7-14] Although this phenomenon appears to be dependent on the gonadal hormone environment,[2, 11-14] the mechanisms involved remain poorly understood. In this study we coupled a moderately intensive sampling paradigm with analysis of the resultant LH concentration time series by use of a multiple-parameter deconvolution procedure to appraise in some detail the determinants of the GnRH secretory-priming event at several stages of the menstrual cycle.

Our current results are consistent with previous studies in women that have documented that the stage of the menstrual cycle,[2] presumably reflecting the gonadal hormone environment,[1] influences the serum concentrations of luteinizing hormone achieved in response to a single bolus of GnRH. The use of deconvolution precedures to "unravel" the GnRH-associated secretory event now provides an enhanced understanding of how this menstrual state-specific modulation occurs. Thus the maximal rate of LH secretion (as distinct from serum LH concentrations per se) achieved in response to GnRH in the midluteal phase is significantly greater than that observed in the early or late follicular phases. In contrast, the duration of the secretory episode in the late follicular phase is prolonged in comparison with the early follicular and midluteal phases. It should be noted that the duration of secretion is considerably shorter than that of the serum concentration peak. Thus the enhanced maximal secretory rate in the midluteal phase and the longer secretory event duration in the late follicular phase are responsible for the greater mass of hormone secreted in these two phases when compared with that secreted in the early follicular phase. Such information about secretion requires a technique such as deconvolution analysis, and cannot be inferred from simple inspection of the serum LH concentration peak.[15] Clearly, these studies do not address the question of which particular intracellular processes subserve the menstrual stage-associated alterations in maximal LH secretory rate and secretory event duration. However, in consideration of this experimental design in which the hypothalamic peptide was administered exogenously, these data do demonstrate that short-term variations in the amount and/or duration of the GnRH stimulus per se are not required to effect variations in the characteristics of the LH secretory event. More prolonged variations in the characteristics of the endogenous GnRH pulse signal throughout the menstrual cycle may act to influence pituitary responsiveness.

Our data also support earlier studies that demonstrated GnRH self-priming in the late follicular-midluteal[2] and midfollicular-midluteal[7] phases of the menstrual cycle. However, our results also provide evidence for a previously undescribed potentiating effect of GnRH on certain secretory event characteristics during the early follicular phase. Specifically, the maximal rate of LH secretion achieved in response to the second bolus of GnRH compared with the first was also enhanced in the early follicular phase and the midluteal phase. However, the duration of the secretory events in response to the two consecutive GnRH challenges did not differ. These results imply that it is the rate with which LH molecules are discharged from the pituitary gland within a given amount of time, rather than the duration of release itself, that results in the observed augmentation of LH secretion with repetitive GnRH administration.

Serum estradiol concentrations were significantly predictive of the mass (as well as maximal rate) of LH secreted after the first GnRH injection in the late follicular and midluteal phases. This finding is consistent with an earlier inference by Lasley et al.[1] that estrogen participates in increasing intrapituitary LH stores that are available for release in response to secretagogue action.[1] Of additional interest is the finding that serum estrogen levels also correlated with the mass of LH released after the second pulse of GnRH in the early follicular phase. This observation suggests that both estrogen and prior exogenous GnRH exposure are required in the early follicular phase to demonstrate an increased availability of LH for release. Serum progesterone concentrations were negatively correlated with LH half-life and secretory burst duration, possibly indicating changes in the posttranslational carbohydrate modification of LH molecules with associated changes in the metabolic clearance rate of LH[17] and alterations in the kinetics of GnRH action and/or gonadotroph secretory responses, which result in a decreased secretory burst duration. In the midluteal phase, progesterone concentrations were related to the mass of LH released after the second GnRH pulse. Thus progesterone also may influence the self-priming actions of GnRH.

The half-lives reported for endogenous LH correspond to half-lives of LH (calculated from stable metabolic clearance rates) of 123 minutes,[18] 136 minutes,[19] and 112 minutes,[20] assuming a 3.5 L distribution volume for LH. Thus our LH half-life values of 60 to 120 minutes agree with independently estimated values obtained by steady-state infusion of various exogenous LH preparations. It should be noted that the deconvolution model used in this study provides estimates of LH half-life under steady-state conditions (or approximately its slower second component rate constant in nonequilibrium studies) and does not reflect acute distribution coefficients (initial equilibration half-times after bolus injection), which could be calculated with even more rapid sampling. This observation presumably reflects the fact that LH distribution is virtually complete between consecutive (10-minute) sample observations. Moreover, our results do not disagree with those of Wehmann et al.,[18] who showed a moderate increase in metabolic clearance rate (or decrease in half-life) in the luteal phase.

We thank Sandra Jackson and the nursing staff at the Clinical Research Center for their expert patient care and Catherine Kern and Ginger Bauer for technical assistance with the assays.

The perinatal impact of cocaine, amphetamine, and opiate use detected by universal intrapartum screening

Katherine M. Gillogley, MD,[a] Arthur T. Evans, MD,[a] Robin L. Hansen, MD,[b] Steven J. Samuels, PhD,[a] and K.K. Batra, PhD[c]
Sacramento, California

Universal urine testing for cocaine, amphetamines, and opiates was performed on 1643 women admitted to an obstetric service for a 1-year period with 20.5% having positive results. There were 299 patients with positive toxicology results matched for race and discharge date with patients having negative toxicology and drug history. Significant differences in age, prior obstetric history, prenatal care, alcohol history, and smoking were noted between groups. There was a significant decrease in birth weight, head circumference, length, and gestational age for the drug-positive group, which was most marked in cocaine and multiple drug users. These differences persisted after we controlled for smoking, prenatal care, and prior preterm births. Differences in birth weight and head circumference remained after we controlled for gestational age. Rates of congenital anomalies and abruptio placental were similar between groups. Perinatal substance abuse is independently associated with growth retardation and prematurity. Multiple risk factors are frequently present, necessitating a comprehensive approach to prenatal care. (AM J OBSTET GYNECOL 1990;163:1535-42.)

Key words: Perinatal substance abuse, cocaine, amphetamines, opiates, low birth weight

Perinatal chemical use appears to be increasing dramatically throughout the United States. Obstetric care providers are being confronted with increasing numbers of women who are using chemical substances during pregnancy. Pediatricians are also encountering increasing numbers of newborn infants with evidence of intrauterine exposure to maternal chemical use.

There are many forms of perinatal chemical use. Improper or abusive use of legal chemicals such as alcohol and cigarettes is common and legally tolerated. The misuse of controlled chemicals such as sedatives, cocaine, amphetamines, marijuana, and narcotics is frequently encountered and appears to be increasing. The use of illegal chemicals (those with no medically sanctioned uses) such as crack cocaine, crystal amphetamine, PCP, and LSD has been less apparent during pregnancy until the past decade.

The complications that have been reported with the perinatal use of these chemicals include: low birth weight, prematurity, stillbirth, abruptio placentae, fetal distress, cerebral infarctions, congenital malformations, neonatal toxicity and withdrawal, sudden infant death syndrome, and neurobehavioral abnormalities.[1-6] However, these complications are not limited to or specific for chemical use. There are numerous confounding factors such as smoking, alcohol use, limited or no prenatal care, low socioeconomic status, or poor reproductive history present in many of the pregnancies that involve chemical use. These confounding factors are recognized to be associated with many of the same complications that have been reported with chemical use alone. Previous studies of perinatal chemical use have been limited in their ability to evaluate the contribution of confounding factors to adverse perinatal outcome. Limited patient numbers and inability to identify the chemical use status of all patients in the study population have interfered with analysis of the impact of confounding factors.

The accurate assessment of the extent of perinatal chemical use, its impact on perinatal outcomes, and the interplay with confounding factors requires population-based data. Without such information, appropriate decisions cannot be made regarding allocation of resources and areas of emphasis for patient identification, intervention, and follow-up programs.

This study investigates chemical use in an obstetric population based in an urban perinatal center. All patients underwent urine testing for cocaine, amphetamines, and opiates at the time of obstetric admission.

Differences in demographic and historical factors, perinatal outcome, and the effect of confounding factors are analyzed.

Methods

The Perinatal Unit of the University of California, Davis, Medical Center (UCDMC) is a tertiary obstetric center providing primary services in the Sacramento area, as well as referral services for northern California. The obstetric population at UCDMC is primarily urban; 93% have Medi-Cal (Medicaid) or no insurance coverage. Transfers from other hospitals for acute perinatal complications account for approximately 10% of patients. The patients are ethnically diverse; 46% are white, 21.8% Hispanic, 21.7% black, 5% Asian, and 5.5% various other groups.

Since November 1987 all women admitted to the Obstetrics Service at UCDMC have been routinely tested by a urine toxicology screen, which included assays for cocaine, amphetamines, and opiates. Newborn infants admitted to the nurseries at UCDMC are similarly tested if the mother's toxicology screen is positive or if the infant demonstrates evidence of chemical effects or withdrawal. The results are used to provide appropriate medical and social services. Mother-infant pairs testing positive for the above receive a social services evaluation. A Child Protective Services evaluation is performed as deemed necessary by social services or the pediatrician. Results are not reported to criminal authorities.

All toxicology screens on mothers and infants are performed by the UCDMC Toxicology and Drug Analysis Laboratory. Initial testing for cocaine, amphetamines, and opiates is performed by homogeneous enzyme immunoassay technique (EMIT d.a.u.; Syva Company, Palo Alto). The specificity for the major metabolite of cocaine, benzoylecgonine, is 99% at concentrations of 0.3 μg/ml. The detection of amphetamines and methamphetamines is confirmed by gas chromatography equipped with a nitrogen-phosphorus detector. The EMIT assay is quite specific for opiates but does not distinguish between morphine and other opiates. Cases were excluded if the patient tested positive for opiates only and had received any opiate-containing medications before collection of the urine sample.

Detailed patient information was retrospectively obtained through chart review and from computerized discharge data. Between Dec. 1, 1987, and Nov. 30, 1988, 2028 patients were discharged from the UCDMC Obstetrics Service. Of these, 1643 (81.1%) had a documented result available from urine testing for cocaine, amphetamines, and opiates. Cases were excluded if the patient was discharged antenatally and delivered elsewhere.

The control group was selected from women with both a negative toxicology screen and drug history who were delivered at UCDMC during the time of the study. They were matched with toxicology-positive patients for race and nearest discharge date. The drug history was taken from the patient's prenatal chart and on admission by the admitting physician. If a history of current or past use of opiates, cocaine, amphetamines, marijuana, or other illicit chemicals was noted, the patient was excluded from the control group and another patient was selected.

Statistical analysis of continuous variables was performed with Student's t test with analysis of variance and Bonferroni's t test for multiple comparisons. For categorical variables, the χ^2 test or Fisher's exact test was used with the Bonferroni correction for multiple comparisons. Case and control Apgar scores were compared by the Wilcoxon two-sample rank sum test specialized to grouped data. Multiple regression with analysis of covariance was used to control for confounding factors.

Results

A total of 379 patients had positive urine toxicology screens out of 2028 total obstetric admissions and 1643 patients tested with known laboratory results. Charts were available for review on 348 of the toxicology-positive patients. Forty patients were subsequently excluded because they had received opiate-containing medication before collection of the urine sample, which was positive only for opiates. An additional patient was excluded because of suspected mislabeling of the initial positive specimen with a negative repeat screen. Thus there were 338 (20.5%) patients with positive urine toxicology screens out of 1643 screened admissions and after the above exclusions.

Charts were available for review for 307 patients with "true-positive" results. Eight patients were excluded from obstetric and neonatal outcome analysis because they were discharged antenatally and delivered elsewhere. Of the remaining 299 patients, 12 were discharged undelivered and returned to be delivered on a subsequent admission. Six of these had negative toxicology screens on the subsequent delivery admission. These 12 patients were included in the statistical analysis.

The control group consisted of 293 patients with both negative toxicology screens and drug histories, matched with the toxicology-positive patients for race and nearest discharge date. Ninety-eight patients with negative toxicology screens gave a history of prior drug use and were therefore excluded during the control selection process. Three potential control group patients with negative toxicology screens were excluded because their infants had positive toxicology screens, two for cocaine and one for amphetamines.

Table I. Maternal age and obstetric history

	Controls	*Total cases*	*Cocaine*	*Amphetamine*	*Opiates*	*Multichemicals*
Age (yr) (n = 591)	23.5	25.7*	25.8*	25.2†	25.5	27.1*
Gravidity (n = 586)	2.8	4.2*	4.3*	3.9*	4.2†	5.1*
Term (n = 586)	1.1	1.8*	1.8*	1.7*	1.4	1.9*
Preterm (n = 586)	0.11	0.28*	0.26†	0.23	0.42†	0.40*
Spontaneous abortion (n = 586)	0.30	0.42†	0.41	0.41	0.58	0.40
Induced abortion (n = 586)	0.39	0.78*	0.78*	0.60	0.79	1.29*
Living (n = 586)	1.1	1.9*	1.9*	1.7*	1.6	2.2*

Values are means.
*$p < 0.01$, comparison with controls.
†$p < 0.05$, comparison with controls.

Toxicology results. Cocaine alone was the most common cause of a positive toxicology screen, being detected in 139 patients (46% of positives). Amphetamine-methamphetamine alone was found in 106 patients (35%). More than one of these chemicals were detected in 35 patients (12%), while only 19 patients were found to be positive for opiates alone.

Age. The mean age was 25.7 years for study patients versus 23.5 years for controls ($p < 0.001$) (Table I). It is of interest that the users of multiple drugs had the highest mean age at 27.1 years.

Obstetric history. There were significant differences ($p < 0.05$) between study and control patients for gravidity, preterm births, abortions (both induced and spontaneous), and number of living children (Table I). The difference in gravidity persisted even after control for differences in maternal age ($p < 0.001$). When primigravid women were excluded, there were no significant differences between the groups for the proportion of preterm births or spontaneous or induced abortions to prior pregnancies. There was a trend that did not reach statistical significance ($p = 0.13$) for an increased proportion of preterm births in the drug-positive group.

Race. Study patients and controls were matched for race. The toxicology-positive patient group comprised 44% blacks, 42% whites, 10% Hispanics, and the remainder either "other" or unknown ethnic definitions. This represents a significant disparity from the racial distribution of the total UCDMC obstetric population, which consists of 22% blacks, 46% whites, 22% Hispanics, and 5% Asians. There were significant racial differences between the users of the different types of chemicals (Fig. 1)

Marital status. Marital status was assigned as single, married, separated, or divorced. There was a difference approaching significance ($p = 0.05$) between the study patients and controls with these categories. There was a significant difference between cases and controls ($p < 0.02$) in married versus unmarried status. Cocaine and multiple chemical users were least likely to be married.

Prenatal care. The majority of patients studied received their prenatal care in the UCDMC Obstetrics Clinic (53.2% of study patients and 73.3% of controls). There was a highly significant difference ($p < 0.001$) between the two groups in failure to obtain prenatal care (Table II). The group of opiates-only patients received the greatest amount of prenatal care. In this group 42% received methadone treatment. The daily contact with their treatment center facilitated their compliance with prenatal care.

Cigarette smoking. There was a high incidence of cigarette smoking reported among all patients. The difference between toxicology-positive patients and controls, however, was significant. Multichemical users had the highest incidence of smoking (Table III).

Alcohol use. The true level of alcohol use in our patient population was not ascertained because testing was not performed for alcohol and detailed information concerning quantity and frequency was not recorded in a significant number of charts. However, 37.3% of toxicology-positive patients reported alcohol use, compared with 10.6% of controls. This represented a statistically significantly different level of self-reported use. Cocaine and multichemical users were more likely than amphetamine users to report alcohol use (Table III).

Drug history. There was substantial denial of chemical use among the toxicology-positive patients. Denial of *any* chemical use at *any* time was obtained from 38.5% of these women (Table III). It is important to note that 25% of the women with a negative toxicology test reported chemical use before or during the index pregnancy.

Pregnancy complications. The incidence of pre-

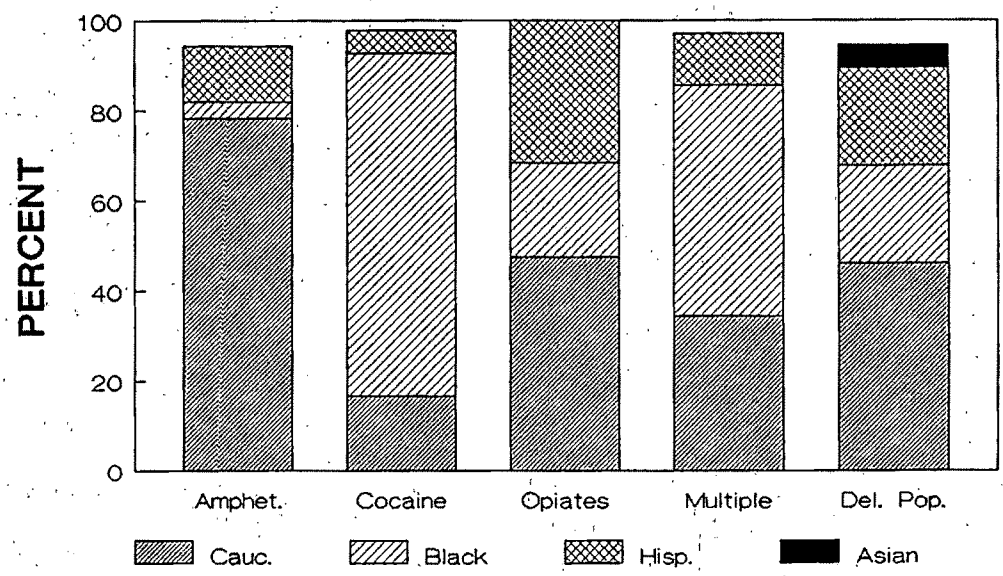

Fig. 1. Comparison of ethnic backgrounds of amphetamine, cocaine, opiate, or multiple substance users as detected by urine toxicology screen on admission to the obstetric service and the overall obstetric population.

†$p < 0.05$, comparison with controls.
‡All patients with drug history excluded during control selection process.

mature labor was significantly increased in the chemical-positive group as compared with the chemical-negative group ($p < 0.006$). The incidence of premature labor was highest in cocaine and multiple chemical users.

The incidence of premature rupture of membranes, abruptio placentae, intrauterine fetal death, and fetal distress was not significantly different between the two groups. Although cocaine and multiple chemical users had more frequent occurrences of these complications, the differences were not statistically significant on comparison with control patients (Table IV). Congenital

Table IV. Pregnancy complications

Complication	Controls (n = 293) (%)	Cases (n = 299) (%)	Amphetamines (n = 106) (%)	Cocaine (n = 139) (%)	Opiates (n = 19) (%)	Multichemicals (n = 35) (%)

Table V. Method of delivery

Method	Controls (n = 299) (%)	Cases (n = 293) (%)	Amphetamines (n = 106) (%)	Cocaine (n = 139) (%)	Opiates (n = 19) (%)	Multichemicals (n = 35) (%)
Spontaneous vaginal	83	83	84	86	74	77
Primary cesarean section	11	7	7	8	16	3
Repeat cesarean section	3	4	5	4	5	3
Forceps	2	3	2	0	5	6
Vacuum	1	1	1	1	0	0
Vaginal breech	1	2	2	1	0	11*

*$p < 0.05$, comparison with controls (Bonferroni correction applied, Fisher's exact test).

anomalies were not increased in the toxicology-positive group. One case of hypospadias was noted in each of the amphetamine group and the control group.

Method of delivery. There was no significant difference in delivery method between toxicology-negative and toxicology-positive groups (Table V). There was a difference when chemical categories were analyzed separately ($p < 0.01$), with an increase in breech vaginal delivery among multiple chemical users.

Birth outcomes. Birth weight, length, head circumference, and gestational age were significantly lower in the toxicology-positive group as compared with the negative group. This difference was most marked in the cocaine and multiple chemical users. The group that was positive for opiates alone had outcomes that were similar to those of controls (Table VI).

The difference persisted for birth weight, length, head circumference, and gestational age when differences in prenatal care, smoking, and prior preterm births were controlled (Table VII). With control for gestational age, significant differences remained between groups for birth weight and head circumference. With analysis of covariance, there was a significant interaction between group and gestational age (Fig. 2).

Low birth weight (<2500 gm) and prematurity (<37 weeks) were significantly increased in the toxicology-positive group ($p < 0.002$). Low birth weight at term (≥37 weeks) was also increased in the toxicology-positive group ($p < 0.01$). These differences persisted in the cocaine and multiple chemical groups when these groups were analyzed separately. Case Apgar scores tended to be lower than control scores at 1 and 5 minutes ($p = 0.08$ and $p = 0.025$, respectively).

Comment

Most previous studies of perinatal chemical use have reported data from risk- or complication-directed toxicology testing. Selective screening by any criteria has the inherent risk of underdetection of the toxicology-positive group and consequent misrepresentation of the perinatal results and complications related to chemical use. Additionally, the influence of confounding factors is impossible to assess with selective testing since the population is not defined and the distribution of all potential factors of influence is not known.

This study examines the prevalence of cocaine, amphetamine, and opiate use, detected by universal urine testing in a defined obstetric population. The criteria for testing were simply admission to the Obstetrics Service at UCDMC. The majority of women were in labor.

Table VI. Perinatal outcome

	Controls	*Cases*	*Amphetamines*	*Cocaine*	*Opiates*	*Multichemicals*
Birth weight (mean, gm) (n = 583)	3165.6	2785.8*	294.7†	2682.6*	3026.7	2575.0*

The peripartum chemical use rate was 20.5%. Nineteen percent of patients admitted to the Obstetrics Service did not have a toxicology result available for reasons such as failure to provide a urine sample before delivery, lack of patient cooperation, refusal to provide urine, and lost specimens. Even in the unlikely event that all of these patients had had negative results, the peripartum prevalence rate would have been 16.6%. We suspect that the positive rate of the untested patients was at least equal to the group for which test results were available.

This study confirms previous suggestions that a drug history alone is not accurate for identifying chemical use among pregnant women. Almost half of the women with positive tests denied chemical use during pregnancy.

One limitation of this study is that chemical use was ascertained from a test on one occasion, linked to hospital admission. Some "controls" might have used cocaine, amphetamines, or opiates earlier in pregnancy. Testing for marijuana was not performed because of limited laboratory capabilities and cost considerations. If testing for marijuana, nicotine, and alcohol were added, it is virtually certain the number of positive tests would have increased significantly. While we believe the use of other potent chemicals such as LSD, PCP, and prescription drugs is relatively low in our population, these drugs are certainly not absent.

Although cocaine use is spreading rapidly throughout the United States, amphetamine use is recognized to be more characteristic of the West Coast and of northern California in particular. Local manufacture of amphetamines is common in northern California. The drug is often used as an alternative to cocaine and generally appears to supplant cocaine use in our population. With the recent introduction of crystal methamphetamine ("ice"), it is anticipated that more widespread use of amphetamines will occur throughout the United States.

This study demonstrated significant differences in several demographic factors between the toxicology-positive and toxicology-negative groups of pregnant women. Chemical-positive women were older, were of higher gravidity, and had much less prenatal care than

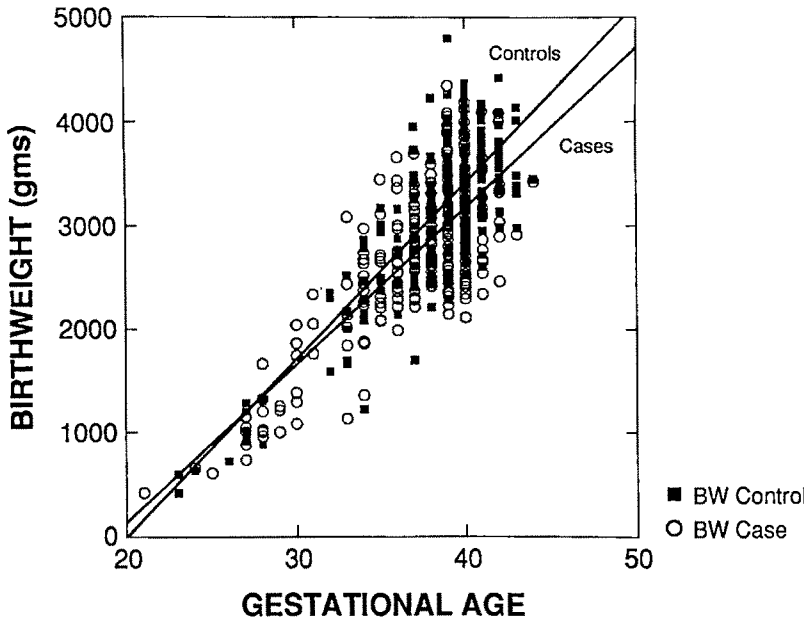

Fig. 2. Relationship of birth weight and gestational age in control patients (toxicology screen and drug history negative) and cases (toxicology screen positive).

the control patients. It appears from these data that these patients are not simply young, vulnerable, and inexperienced women who are casually experimenting with these chemicals. The greater mean age and parity, compared with those of the control group, suggest the possibility of a more chronic or long-standing pattern of chemical use in these women. Progression to cocaine and amphetamine usually occurs after a period of alcohol, cigarette, and marijuana use.[7] The pattern of progressive chemical use suggests that many of these women who are identified as cocaine or amphetamine users today may progress to the use of narcotics to counteract the intense highs of cocaine and amphetamines.

The differences in smoking and alcohol use between the two groups were remarkable. Smoking proved to be the single finding most strongly correlated with a positive urine toxicology result. It is highly likely that the actual use of alcohol among all groups was substantially greater than reported by patients. Many women recognize that alcohol should be avoided during pregnancy. The degree of denial for cocaine, amphetamine, and opiate use among toxicology-positive patients suggests that the same situation exists with the reporting of alcohol use.

There were significant variations in race among the toxicology-positive patients when analyzed by the drug for which they were positive. These racial differences in the "drug of choice" are likely to be regional and may vary widely.

The finding that toxicology-positive patients were less likely to be married has important implications. A large number of chemically positive mothers are likely to be parenting alone or with inconsistent support from partners. We were not able to evaluate the level of family support available to these women, but these findings suggest a need for greater social and economic support services.

Although factors that place the pregnancy at risk such as smoking, limited prenatal care, and prior preterm births were increased in the toxicology-positive group, there remained a significant direct adverse effect of substance abuse on birth weight, head circumference, length, gestational age, and Apgar scores. For length and Apgar scores, this effect appeared to be mediated through the decreased gestational age. However, for birth weight and head circumference, there was a decrease that was independent of gestational age. This difference in birth weight increased with gestational age. It appears that head circumference is not spared with the growth retardation associated with chemical abuse.

The incidence of premature rupture of the membranes did not statistically increase in the toxicology-positive group. This supports the theory that the mechanism for premature labor associated with chemical use is related to increased uterine irritability in association with vascular spasm or a direct effect on myometrium instead of an infectious cause. Abruptio placentae was not increased significantly, in contrast to some previous reports.[4, 6] Reports that have demonstrated such an increase have used selective screening, possibly under-

representing the incidence of substance abuse in the general obstetric population. Alternatively, the failure to detect an increase in abruptio placentae in our study and another population study[8] may be a type II error resulting from the low frequency of the complication in either group.

The incidence of congenital anomalies was similar in the two groups. Previous studies have reported conflicting results. Zuckerman et al.[1] found a marked increase in major or multiple anomalies in cocaine users, without an increase in overall incidence of anomalies. Neerhof et al.[8] found no increase in anomalies in infants exposed to cocaine only but did find an increase with exposure to multiple substances. Others[9, 10] have found an increase in genitourinary anomalies with first-trimester cocaine use. No increases in such anomalies were noted in this study. Neonatal renal ultrasonography was not performed routinely; however, antenatal ultrasonography was performed in the majority of patients receiving prenatal care.

The findings in this study have several important therapeutic implications. Because chemical use has an independent adverse effect on pregnancy outcome, identification and intervention early in the pregnancy offer the mother and fetus the greatest potential for a good pregnancy outcome.[6, 11] Women engaging in perinatal chemical use often have additional risk factors such as smoking, alcohol use, and prior preterm birth. These need to be addressed in a comprehensive fashion during obstetric care. Patient education should include information about the warning signs of preterm labor and instruction for self-palpation of uterine contractions.[12] Serial ultrasonography should be used to evaluate fetal anatomy and growth. Antenatal fetal testing is used for the usual obstetric indications.

Although not addressed in this study, decreased pregnancy weight gain has been reported in cocaine and marijuana users.[1] Birth weight and gestational age were increased in a group of women with poor weight gain who were subsequently enrolled in an intensive nutrition intervention program, on comparison with a similar group of controls receiving routine prenatal care.[13] Thus intense nutritional surveillance and education should be a part of the obstetric management of the pregnant substance abuser.

In summary, with universal urine toxicology testing on admission to an obstetrics service, we documented a significant level of cocaine, amphetamine, and opiate use. Smoking, limited prenatal care, alcohol use, and prior preterm births were significantly increased in this group of women, placing the pregnancy at risk for complications in addition to the direct effects of chemical use. An independent, adverse effect of these chemicals on fetal size and gestational age at delivery was found. The effect on fetal size appears to be mediated through both preterm birth and growth retardation. Comprehensive outreach, identification, and treatment programs are required to prevent the consequences of perinatal chemical use.

We thank Sunny Eidson, Elizabeth Perry, Carolyn Hughes, and Gary Hughes for their assistance.

Prenatal diagnosis of fetal intracranial calcifications

Yasutsugu Koga, MD, Masahiko Mizumoto, MD, Yoshinori Matsumoto, MD, Tetsuo Hattori, MD, Shinichi Tanaka, MD, Toshinobu Tanaka, MD, and Seiichiro Fujimoto, MD

Sapporo, Japan

A case is presented wherein fetal intracranial calcifications as a result of intrauterine cytomegalovirus infection were visualized by computed tomography and magnetic resonance imaging at 36 weeks' gestation. Diagnosis of in utero cytomegalovirus infection was made by isolation of the virus from amniotic fluid. No symptomatic abnormality has been noted in the neonatal period except periventricular calcifications. (Am J Obstet Gynecol 1990;163:1543-5.)

Key words: Intracranial calcification, congenital cytomegalovirus infection, fetal cranial computed tomography and magnetic resonance imaging, prenatal diagnosis

Fetal intracranial calcifications are rare findings and are difficult to clarify by antenatal ultrasonography. We present a case in which periventricular calcifications as a result of intrauterine cytomegalovirus infection were clearly visible by fetal cranial computed tomography and magnetic resonance imaging.

Case report

A 29-year-old Japanese woman, gravida 2, para 2, was referred to our clinic at 36½ weeks' gestation because a previous ultrasonographic examination performed elsewhere had identified ventriculomegaly. The course of pregnancy had been uneventful and, in particular, there was no history of fever, rash, and malaise.

Our ultrasonogram revealed a single fetus with biometry that was consistent with gestational age. Intracranial scans showed bilateral dilatation of the lateral ventricles. Although small areas close to the periventricular wall appeared hyperechogenic, we could not discriminate between calcifications and artifacts. To confirm whether calcifications existed, we performed cranial computed tomography and magnetic resonance imaging of the fetus.

Computed tomography visualized discrete high-density spots scattered along the periventricular wall (Fig. 1). On magnetic resonance imaging, a high-intensity area formed on part of the wall of the left lateral ventricle with dilatation was clearly visible by means of T_1-weighted images (600 msec repetition-time, 15 msec echo-time) (Fig. 2). Both findings were diagnosed as foci of calcifications. An intrauterine cytomegalovirus infection was thought to be the most likely cause of these images.

On maternal serologic screening for infections, the hemagglutination inhibition test for rubella was positive at 1:8, and both toxoplasma immunoglobulin (Ig) G and IgM antibodies were negative by fluorescent antibody technique. The cytomegalovirus titer with enzyme-linked immunosorbent assay (ELISA) was IgM-negative and IgG-strongly positive. Transabdominal amniocentesis performed for a viral culture yielded a positive culture for cytomegalovirus.

At 39½ weeks' gestation a 3020 gm male infant with an Apgar score of 8 at 1 minute was delivered by induction of labor. Bilateral dilatation of the lateral ventricles and periventricular calcifications were verified in the neonate by computed tomography, but no other abnormalities such as hepatosplenomegaly, hyperbilirubinemia, petechial rash, microcephaly, or chorioretinitis were noted. Both IgG and IgM antibodies for cytomegalovirus with enzyme-linked immunosorbent assay were positive in the cord blood, and intrauterine cytomegalovirus infection was identified on the basis of viruria detected at birth. At 12 months of age the infant showed signs of psychomotor retardation with a spastic tetraplegia.

Comment

Cytomegalovirus is known to be one of the main causes of congenital infections. Although 95% of pregnant Japanese women are immune to cytomegalovirus, the incidence of intrauterine cytomegalovirus infection in Japan is about 0.5%, similar to that reported in Europe and America.[1]

Clinical features of congenital cytomegalovirus infection vary, ranging from a silent infection to classic cytomegalic inclusion disease. Periventricular calcifi-

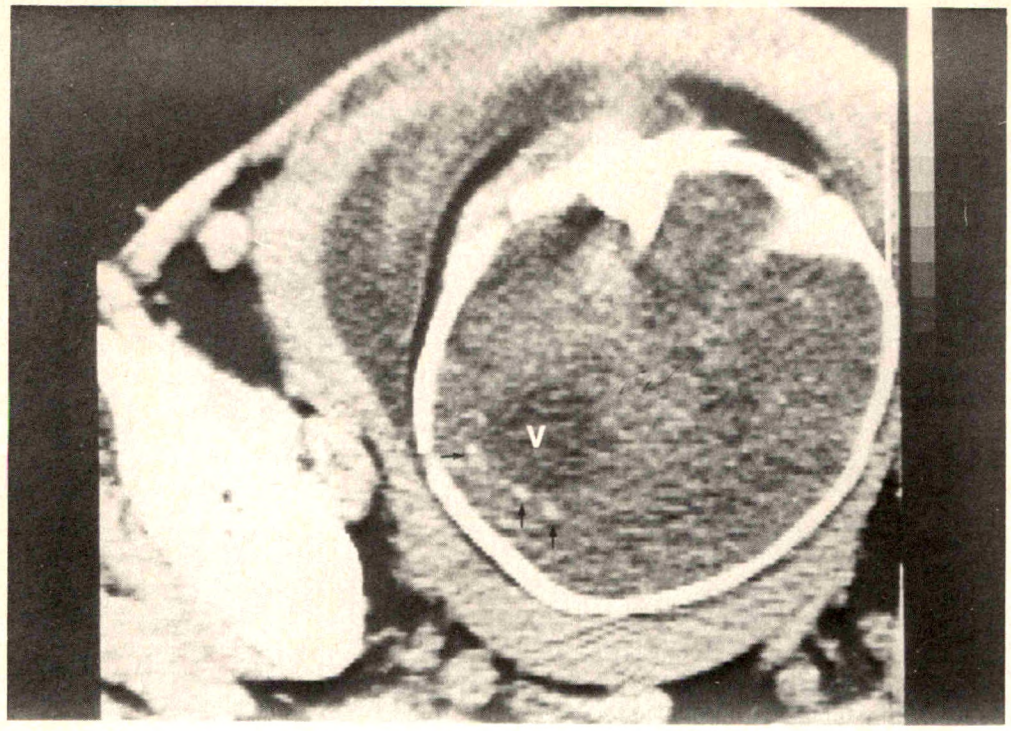

Fig. 1. Fetal cranial computed tomography. Enlargement of left lateral ventricle *(V)* and discrete high-density spots *(arrows)* scattered along periventricular wall are clearly visible.

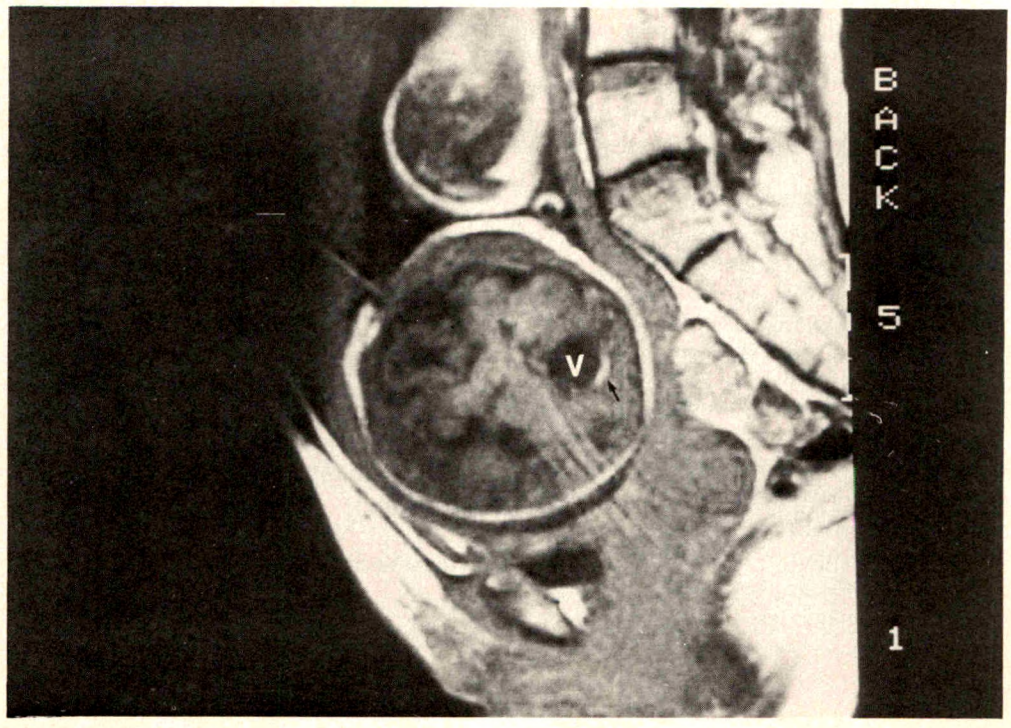

Fig. 2. T_1-weighted magnetic resonance imaging (600 msec repetition-time, 15 msec echo-time) of fetal brain. High-intensity area *(arrow)* forms part of wall of left lateral ventricle with dilatation *(V)*.

cations, characteristic of severe congenital cytomegalovirus encephalitis, are frequently observed with microcephaly. Besides cerebral calcifications, in our case the infant manifested not only microcephaly but other clinical features of symptomatic congenital cytomegalovirus infection in the neonatal period. Therefore the neonate probably would be recognized as a healthy newborn infant if intrauterine cytomegalovirus infection was not prenatally proved.

It is possible that prenatal diagnosis of congenital cytomegalovirus infection can be made by recovery of the virus from amniotic fluid.[2] At present there are a few reports in the literature that describe the isolation of cytomegalovirus from amniotic fluid. However, we are not aware of a case previously reported in which fluid from an amniocentesis performed on a pregnant woman without a symptomatic cytomegalovirus infection because of fetal periventricular calcifications was positive for cytomegalovirus, as was found in this case.

Fetal cerebral calcifications are very difficult to identify with ultrasonography because flecks of calcifications are too small to cause acoustic shadowing. In our case, fetal cranial computed tomography visualized foci of periventricular calcifications. On magnetic resonance imaging, T_1-weighted images clearly showed an area of high intensity along the periventricular wall, although magnetic resonance imaging is generally unfavorable to show calcifications because of the low proton density of calcium.

On the basis of our experience, the combination of fetal intracranial ultrasonography and magnetic resonance imaging is of clinical value to establish a less invasive diagnosis of cerebral calcifications.

Inhibition of aromatase activity by 8-bromo-cyclic adenosine monophosphate in cultured first-trimester human trophoblast

Marie R. Rodway, MSc, Basil Ho Yuen, MB, and Peter C. K. Leung, PhD
Vancouver, British Columbia, Canada

We have previously shown that 8-bromo-adenosine-3′:5′-cyclic monophosphate inhibits production of estradiol from androgen precursors in trophoblast isolated from term placentas. In these experiments we sought to evaluate the effect of 8-bromo-adenosine-3′:5′-cyclic monophosphate on aromatase activity in first-trimester trophoblast culture. Trophoblast cells were enzyme dispersed from first-trimester placentas and purified on a Percoll gradient. On the third and fourth day after dispersion cultures were treated with androstenedione or testosterone with and without 2 mmol/L 8-bromo-adenosine-3′:5′-cyclic monophosphate. The quantity of estradiol, estrone, progesterone, human placental lactogen, and human chorionic gonadotropin was determined by radioimmunoassay. We concluded that in first-trimester trophoblast, as previously reported in term trophoblast, 8-bromo-adenosine-3′:5′-cyclic monophosphate inhibited the production of estradiol from the supplied androgen precursors. Human chorionic gonadotropin and human placental lactogen production was stimulated by 8-bromo-adenosine-3′:5′-cyclic monophosphate. Progesterone production was either stimulated or was unchanged by the presence of 8-bromo-adenosine-3′:5′-cyclic monophosphate. (AM J OBSTET GYNECOL 1990;163:1546-51.)

Key words: Placental cell culture, aromatase, cyclic adenosine monophosphate, trophoblast

During pregnancy the placenta is the primary site of estrogen synthesis after the first trimester. The placenta is deficient in $C_{17,20}$-lyase and 17α-hydroxylase, and is therefore dependent on androgen synthesis, primarily in the fetal compartment, for precursors that are aromatized to estrogens in the placenta.

Cyclic adenosine monophosphate is a well-known second messenger that affects hormonogenesis in cultured trophoblast. Stimulation[1-3] or inhibition[4,5] of aromatase activity has been reported in response to cyclic adenosine monophosphate treatment of trophoblast in culture.

Cyclic adenosine monophosphate also affects the production of human chorionic gonadotropin (hCG), progesterone, and human placental lactogen (hPL). The production of hCG in cultured cells is stimulated by treatment with cyclic adenosine monophosphate,[4-8] as is the production of progesterone.[5,6,8] Production of hPL by cultured cells has been reported to be stimulated,[9,10] inhibited,[2,11] or unaffected[12] by the presence of cyclic adenosine monophosphate.

Hormone production and regulation of this production in the trophoblast is believed to be dependent on the gestational age of the placenta.[13] Some studies have sought to determine the effect of cyclic adenosine monophosphate in cell cultures prepared from first-trimester placentas. Human chorionic gonadotropin production was stimulated by cyclic adenosine monophosphate in cultured cells from first-trimester placentas.[14]

In this study we examined the effect of 8-bromo-adenosine-3′:5′-cyclic monophosphate (8-br-cAMP) on the production of estradiol and estrone from androgen (androstenedione, testosterone) precursors in first-trimester human trophoblast cell cultures. For comparison, the effects of 8-br-cAMP on hCG, hPL, and progesterone output by the cells were also determined.

Methods and material

Trophoblast cells were prepared according to the method of Kliman et al.[15] with some modifications. Tissue was collected immediately after vacuum aspiration. Membranes were excluded and trophoblast tissue was finely minced and digested in Hanks' balanced salt solution (Gibco Laboratories, St. Lawrence, Mass.) containing 0.25% trypsin (Gibco) and 500 U/dl of deoxyribonuclease type I (Sigma Chemical Company, St. Louis) at 37° C for five 10-minute digestions. After each digestion the supernatant was centrifuged at 1000

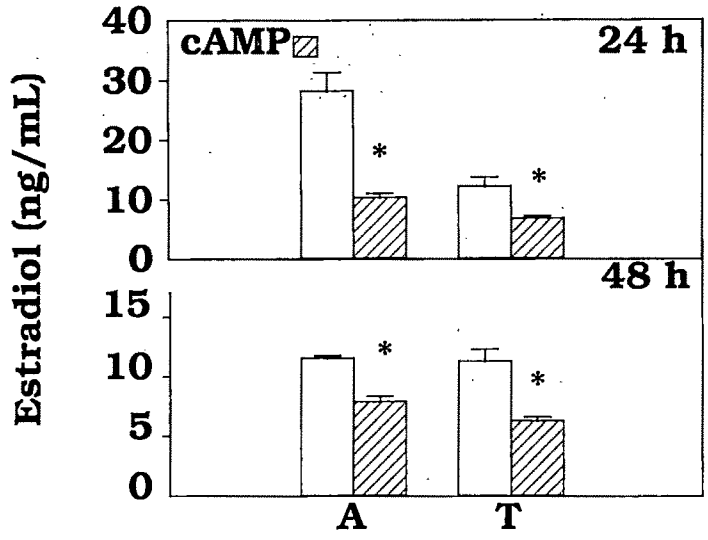

Fig. 1. Effect of 8-br-cAMP on production of estradiol from androstenedione or testosterone by cultured first-trimester trophoblast in culture in presence of 10% fetal calf serum. This figure is representative of four experiments that produced similar results. *Asterisk*, $p < 0.01$, androgen versus androgen with 8-br-cAMP.

g for 10 minutes over 1 ml of calf serum. Collected cells were pooled and placed on a Percoll gradient. Cytotrophoblast were collected and centrifuged at 1000 *g* to remove Percoll and were resuspended in Dulbecco's modified Eagle medium (Gibco) supplemented with 10% fetal calf serum, and then counted and plated in 24 multiwell culture plates (Falcon, Becton-Dickinson, Rutherford, N.J.) at a density of 0.5 million cells/ml/well. Cells were cultured for 24 hours (37° C, 5% carbon dioxide in air) and the media was then changed to Dulbecco's modified Eagle medium without serum supplement (designated as "serum-free" cultures), or to Dulbecco's modified Eagle medium supplemented with 10% fetal calf serum. Cultures were treated at 48 and 72 hours and media were collected at 72 and 96 hours. The medium was stored at −20° C until hormones could be analyzed by radioimmunoassays. Experiments were done in quadruplicate and four experiments with and without serum supplement were done. hCG was analyzed by means of β-hCG kits (Amerlex, purchased from Amersham, Arlington Heights, Ill.). Estradiol, estrone, and progesterone concentrations were determined by radioimmunoassay with antisera provided by D. T. Armstrong (University of Western Ontario). hPL was analyzed by radioimmunoassay with hPL and hPL antiserum supplied by the National Institute of Diabetes Research. The percentage of intraassay and interassay variance, respectively, was 8.4% and 12.2% for estradiol, 7.0% and 7.4% for estrone, 6.4% and 7.9% for progesterone, 5.2% and 7.3% for hCG, and 6.6% and 10.4% for hPL.

Results

In four experiments in which 10% fetal calf serum was present during the treatment period, there was an apparent suppression of aromatase activity in the presence of 2 mmol/L 8-br-cAMP. In all cases there was a significant ($p < 0.01$) decrease in the conversion of androgen precursors (androstenedione and testosterone) to estradiol (Fig. 1). Cultures were treated 48 and 72 hours after plating and the suppression was evident after the first 24 hours of exposure to 8-br-cAMP. In three of these four experiments a significant suppression of estrone formation also occurred (Fig. 2). In serum-free cultures, this effect on the production of estradiol was observed in three of the four experiments after 24 hours' exposure to 8-br-cAMP, but not after 48 hours (data not shown). Decreased production of estrone from androstenedione and testosterone was seen after 48 hours of culture in only one experiment (data not shown).

Addition of 2 mmol/L 8-br-cAMP stimulated production of hPL. In the presence of fetal calf serum, this increase occurred in one of three cultures at 24 hours and in all at 48 hours (Fig. 3). In the serum-free cultures, hPL was significantly increased at 24 hours in three of four cultures and in all cultures by 48 hours of exposure to 8-br-cAMP (data not shown). There was no apparent effect of the presence of androstenedione or testosterone on the production of hPL.

8-Br-cAMP significantly stimulated production of hCG in the presence and absence of serum in all but one experiment at 24 and 48 hours of treatment (Fig.

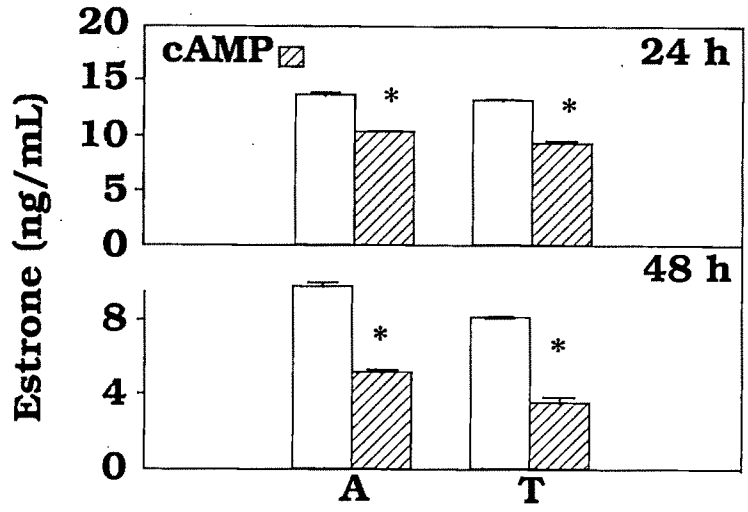

Fig. 2. Effect of 8-br-cAMP on the production of estrone from androstenedione or testosterone by cultured first-trimester trophoblast in culture in presence of 10% fetal calf serum. This figure is representative of four experiments. In three of four experiments significant suppression of estrone formation was seen. *Asterisk*, $p < 0.01$, androgen versus androgen with 8-br-cAMP.

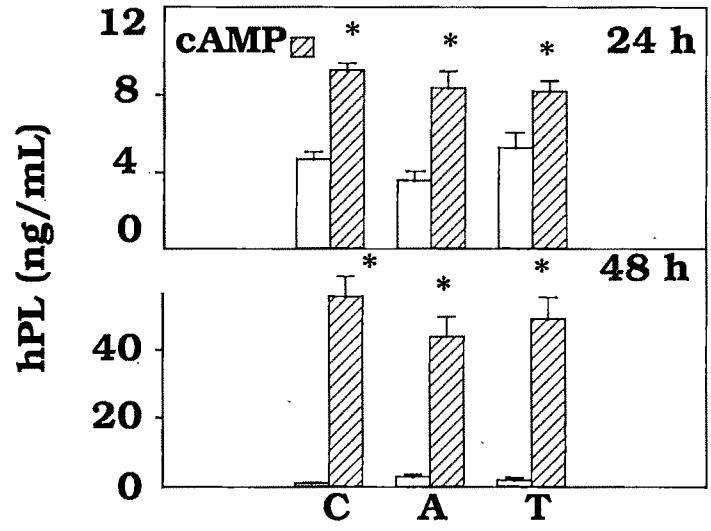

Fig. 3. Effect of 8-br-cAMP on production of hPL by cultured first-trimester trophoblast in the presence of 10% fetal calf serum. This figure is representative of three experiments. In the remaining experiments a significant stimulation of hPL production was not seen until cells had been exposed to 8-br-cAMP for 48 hours. *Asterisk*, $p < 0.01$, control versus 8-br-cAMP treated.

4). Significant stimulation of progesterone production occurred in only two of four cultures in which 10% serum was used (stimulation of progesterone did not occur in this culture, Fig. 5) and in three of four serum-free cultures (at 24 and 48 hours of treatment; data not shown). There was no apparent effect of the presence of androstenedione or testosterone on the production of hCG or progesterone.

Comment

As previously reported in first-trimester trophoblast cell cultures,[14] cyclic adenosine monophosphate caused increased production of hCG in this study. Similarly, the stimulatory effect of 8-br-cAMP on hPL production has been reported in term placental cell culture[9, 10] and has proved consistent in our study of first-trimester cultures prepared in the same manner.[8] The stimulatory effect of cyclic adenosine monophosphate on progesterone production was not as consistent in our first-trimester trophoblast cultures, as has been reported in term trophoblast cultures.[5, 6, 8]

The effect of cyclic adenosine monophosphate on aromatase in first-trimester placental cultures and on term placental cell cultures as reported previously[4, 7, 8]

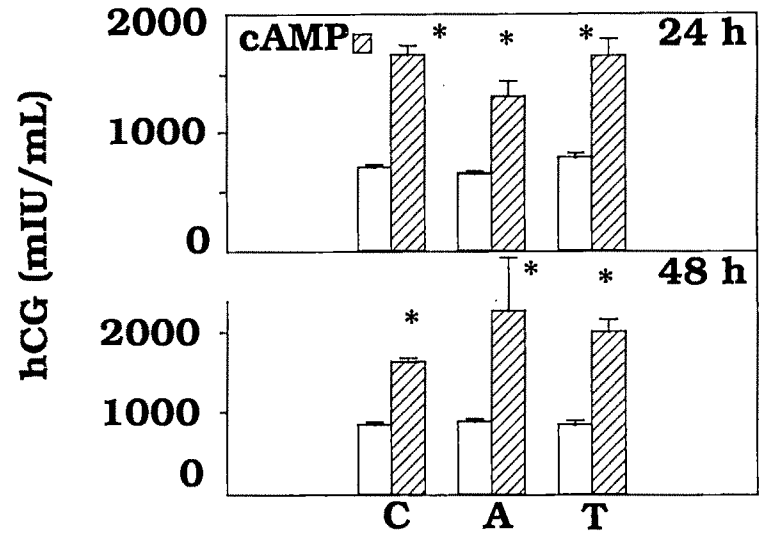

Fig. 4. Effect of 8-br-cAMP on production of hCG by cultured first-trimester trophoblast in presence of 10% fetal calf serum. This figure is representative of four experiments, three of which showed stimulation of hCG production in the presence of 8-br-cAMP. *Asterisk*, $p < 0.01$, control versus 8-br-cAMP treated.

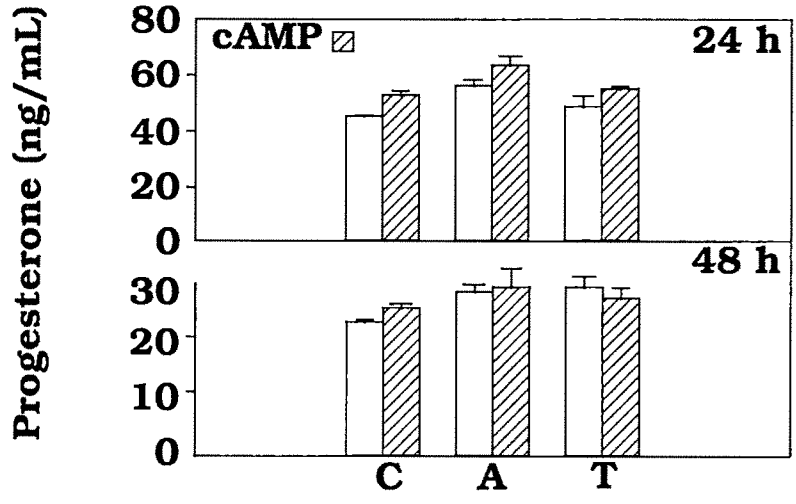

Fig. 5. Effect of 8-br-cAMP on production of progesterone by cultured first-trimester trophoblast in presence of 10% fetal calf serum. This figure is representative of four experiments. In two experiments stimulation of progesterone production occurred. *Asterisk*, $p < 0.01$, control versus 8-br-cAMP treated.

is in contrast to the effect seen in other cell types[16] and in term cells prepared in a manner almost identical to our own.[3] By use of a tritiated water release assay, Lobo and Bellino[3] found that cyclic adenosine monophosphate stimulated aromatase activity in cultured term placental cells. Corbin et al.[17] showed that only one gene codes cytochrome P_{450} aromatase; consequently, only one cytochrome P_{450} enzyme is produced. This eliminates the possibility of expression of different cytochrome P_{450} aromatase genes in different tissues as an explanation for these opposing results.

Fournet-Dulguerov et al.[18] used highly specific antibodies and found cytochrome P_{450} aromatase exclusively in syncytiotrophoblast. Although marked aromatase activity exists in freshly dispersed 95% pure cytotrophoblast,[15] unstimulated aromatase activity does increase by approximately fifteenfold from time of dispersion to 48 hours after dispersion.[3] It has been suggested that cyclic adenosine monophosphate accelerates "functional differentiation" from cytotrophoblast to syncytiotrophoblast.[6] Lobo and Bellino[3] treated cells 24 hours after dispersion and observed a stimulation

of aromatase activity, which could reflect increased functional differentiation. Our cells were initially exposed to cyclic adenosine monophosphate 48 hours after dispersion. Maximal morphologic syncytial formation occurs at 72 hours.[6] The cells may still have been subject to accelerated functional differentiation on exposure to cyclic adenosine monophosphate, but under such conditions stimulation and not the inhibition that was evident would be expected. It is possible that cyclic adenosine monophosphate has different effects that are dependent on the differentiation of the trophoblast.

Ringler et al.[19] studied the effect of 8-br-cAMP on production of the α subunit of hCG, hCG, and cytochrome P_{450} side chain cleavage enzyme messenger ribonucleic acids. They suggested that the mechanism(s) by which cyclic adenosine monophosphate affects hormonogenesis in trophoblast cells is via activation of a protein kinase that phosphorylates a protein that may act at cyclic adenosine monophosphate response elements in the involved genes. Evans et al.[20] have shown that in stromal adipose cells the level of messenger ribonucleic acid translation correlates with the activity of the aromatase system. Perhaps measurement of cytochrome P_{450} (aromatase) messenger ribonucleic acid in these cells will provide more information on the regulation of aromatase activity by cyclic adenosine monophosphate.

Mendelson et al.[16] previously investigated the effect of fetal calf serum, growth factors, and phorbol esters on aromatase activity in human adipose stromal cells. They found that cyclic adenosine monophosphate stimulated aromatase activity and that fetal calf serum attenuated the stimulatory effect of cyclic adenosine monophosphate on the aromatase activity. Epidermal, fibroblast, and platelet-derived growth factors also inhibited this stimulation. Phorbol esters potentiated the stimulatory effect of cyclic adenosine monophosphate on aromatase activity. Lobo and Bellino[3] found that the presence of serum was slightly additive to the stimulatory effect they observed. The presence of fetal calf serum in our cultures seemed to prolong the inhibitory effect of 8-br-cAMP on the inhibition of production of estradiol from androstenedione and testosterone.

In summary, our results indicate that in first-trimester trophoblast, cyclic adenosine monophosphate stimulates hCG and hPL production but suppresses the production of estradiol from androgens, presumably at the aromatization step. These effects are also seen in trophoblast prepared from term placentas, thus supporting a role of cyclic adenosine monophosphate as an intracellular regulator of placental hormonogenesis.

We thank Dr. David Chitayat for assistance in obtaining tissue samples, and Sandra Crespo for assistance in preparing the figures.

A reappraisal of the need for autologous blood donation in the obstetric patient

Robert L. Andres, MD, Kathleen M. Piacquadio, MD, and Robert Resnik, MD
San Diego, California

There has been recent interest in autologous blood donation in obstetric patients, but little attention has been paid to whether such programs are needed or whether the patients that will require transfusion can be accurately predicted. At the University of California San Diego Medical Center from July 1 to Dec. 31, 1988, there were 2265 deliveries; 13 women (0.57%) received blood transfusions. Traditionally accepted risk factors were identified in 251 patients, with only four (1.6%) requiring transfusion. Among the 150 patients delivered by repeat cesarean section, only one (0.7%) required blood. One of 27 (3.7%) multiple gestations, two of eight (25%) patients with placenta previa, and none of the 66 grandmultiparous women had transfusions. These data suggest that autologous blood donation may not be beneficial or cost effective when the low frequency of blood transfusions in this high-risk obstetric population and the difficulty in accurately predicting those likely to require transfusions are considered. (Am J Obstet Gynecol 1990;163:1551-3.)

Key words: Transfusion, hemorrhage, obstetrics

Concern over the transmission of hepatitis and human immunodeficiency virus via the transfusion of homologous blood products is primarily responsible for the interest in the autologous donation of blood. The number of autologous donation programs nationwide increased fourfold from 1974 to 1982.[1] The predepositing of blood by obstetric patients was reported by Miles et al.[2] in 1986, and the focus of the literature since that time has been the issue of safety for the mother and fetus.[3-5] Although the safety question has been addressed, the need for such a program is uncertain. The purposes of our investigation were to determine the frequency of blood product use in a high-risk obstetric service and to evaluate the utility of standard risk factors in identification of patients who require transfusion.

40	Repeat cesarean section	20.7	1	Repeat cesarean section	Donor-specific blood

Dec. 31, 1988 were reviewed. Pertinent clinical data included maternal age, parity, source of prenatal care, gestational age at delivery, mode of delivery, estimated blood loss at delivery, hematocrit level before and after transfusion, and the number of units of packed red blood cells transfused. In addition, risk factors for peripartum transfusion were evaluated, including a history of postpartum hemorrhage, anemia, scheduled cesarean section, placenta previa, grandmultiparity, and multiple gestation. Patients were considered to have been ineligible for participation in an autologous donation program if their hematocrit level was <34%, estimated gestational age was <28 weeks, or if they had not received prenatal care.

Results

The incidence of blood transfusion during the study period was 13 in 2265 cases (0.57%). Transfusions were given in five of 1750 (0.28%) vaginal deliveries, 7 of 356 (1.9%) primary cesarean sections, and 1 of 150 (0.66%) repeat cesarean sections (Table I). The details of the thirteen patients undergoing transfusion of packed red blood cells are outlined in Table II. Twelve of the 13 (92%) patients required more than one unit of red blood cells. The mean (±SE) hematocrit before the transfusion was 21.0% ± 3.0% and the mean hematocrit after the transfusion was 27.6% ± 4.7%.

Of the 251 patients with identifiable risk factors for postpartum hemorrhage, 4 (1.6%) required transfusion. One of the 150 women (0.7%) with repeat cesarean sections, 1 of 27 (3.7%) multiple gestations, and two of eight (25%) patients with placenta previa were transfused. None of the 66 grandmultiparous women required blood transfusion (Table III).

Only two of the patients with identifiable high-risk factors (patients 3 and 13) would have been candidates for participation in an autologous blood donation program. The presence of a hematocrit <34% would have excluded both patients 6 (placenta previa) and 12 (twin gestation).[6]

Comment

The interest in autologous blood donation before elective operation is in large part a result of concern over the transmission of infectious disease. As the number of institutions offering such programs increases, the safety of the practice has been well documented. In a study of >300 high-risk patients who predeposited blood before elective surgery, only 4% experienced minor reactions and there were no serious adverse reactions.[7] Similarly, the safety of phlebotomy for predepositing of blood in the obstetric patient has been shown to be safe for mother and for fetus. Kruskall and Leonard[5] performed continuous fetal heart rate

monitoring during 61 donations and demonstrated reactive patterns throughout the procedure. The incidence of vasovagal reactions during phlebotomy has been shown to be similar for the pregnant and nonpregnant patient.[4]

The overall incidence of blood transfusions in our obstetric service of 0.28% for vaginal deliveries and 1.6% for cesarean sections is lower than that reported by other authors. Palmer et al.[8] cited a 0.3% to 1.6% rate of transfusion after vaginal deliveries and 4.6% to 7.3% after cesarean sections. Among the general obstetric population, Kruskall and Leonard[5] found that 1.2% of vaginal delivery patients and 2.2% of those having cesarean sections required transfusion. Our lower frequency of blood transfusion may reflect a greater tolerance of lower hematocrit values in the postpartum patient.

Rates of transfusion among patients who have banked their own blood range from 2.7% to 7.7%.[5, 9] Reports of higher transfusion rates are often associated with the liberal use of blood for hematocrit values that would be tolerated in the general obstetric population. In a study of 30 patients who participated in an autologous donation program, 15 (50%) had transfusions in the postpartum period. The authors[3] noted that patients who received their own blood had hematocrit values between 28% and 32%, whereas those who received homologous blood were symptomatic with hematocrits <27%. McVay et al.[4] showed that the overall rate of transfusion in their patients who participated in the donation program was 11%, yet only 4.3% had hemoglobin values <8 gm/dl before transfusion.

Our data suggest that the commonly accepted risk factors for postpartum hemorrhage and transfusion requirements do not permit clinicians to identify which patients will require blood transfusion. Fewer than 2% of the patients commonly targeted for participation in autologous donation programs (scheduled repeat cesarean section, placenta previa, multiple gestation, and grandmultiparous women) eventually required transfusion. Thus an attempt to use specific risk factors to select patients likely to need autologous blood would not have been accurate in our study population.

Our data show that the transfusion of a single unit of packed red blood cells is rare; 92% of our patients required multiple units. Because of the lower hematocrit values among obstetric patients and the tendency to restrict phlebotomies to the third trimester of pregnancy, it may be difficult to obtain multiple units per patient. Only 57% of the patients in the group of Herbert et al.[3] were able to donate more than one unit of blood. Thus is is likely that homologous blood would be required in addition to autologous transfusions.

Table III. Incidence of blood transfusion in patients with risk factors for postpartum hemorrhage

Risk factor	*No. of patients*	*Transfusions*	
		No.	*%*
Repeat cesarean section	150	1	0.7
Multiple gestation	27	1	3.7
Placenta previa	8	2	25
Grandmultiparity	66	0	
TOTAL	251	4	1.6

We believe, as has been suggested by others,[10] that careful restriction of blood products in an obstetric population is likely to reduce the frequency so that transfusion is rarely required. The inability to accurately predict which patients will require blood transfusion, combined with the low incidence of transfusions, suggests that the practice of autologous donation of blood among obstetric patients may not be justified.

The Maylard incision in gynecologic surgery

B. Frederick Helmkamp, MD, and Hans-B. Krebs, MD
Falls Church, Virginia

The transverse muscle-splitting Maylard incision was used in 175 gynecologic patients who required pelvic-abdominal surgery. One hundred fifty-three patients (87%) had pelvic malignancy; other indications for operation included uterine myomas, endometriosis, tuboovarian abscess, and benign ovarian cysts. Exposure was excellent: 54% of patients underwent pelvic lymphadenectomy and 17% underwent paraaortic lymphadenectomy. Twelve patients (6.9%) had wound complications, but there was neither long-term morbidity nor mortality associated with the incision. Fifty-six patients (32%) received preoperative or postoperative pelvic radiation therapy with no detrimental effect on wound healing. The Maylard incision is cosmetic, strong, easily learned, and has an acceptable complication rate. Unless a vertical incision is indicated, the Maylard technique is preferred when optimal exposure and accessibility to the pelvis are required. (AM J OBSTET GYNECOL 1990;163:1554-7.)

Key words: Maylard incision, pelvic abdominal surgery

One of the most critical factors in successful surgery is adequate exposure. In 1907 Ernest Maylard, the British surgeon, advocated cutting the rectus muscles with a transverse abdominal incision.[1] This new technique greatly facilitated exposure within the abdomen and pelvis, especially when compared with the more commonly performed Pfannenstiel incision, which was initially described in 1900. Maylard also stressed two other factors in his departure from vertical incisions: a significant decrease in incisional hernia, and more rapid healing by secondary intention with improved cosmetic results if wound infection did occur. Subsequent articles emphasized the anatomic and physiologic advantages of the Maylard incision and its low complication rate.[2-5] In 1954 Tollefson and Russell[6] published data on the Maylard incision used in more than 600 gynecologic and obstetric procedures. Wound complications were minimal (5%), and only one of two patients in whom a hernia developed needed surgical correction. In 1981 Mann et al.[7] reported their experience with the Maylard incision in 168 patients who had radical hysterectomy.

This article reports a prospective study on the Maylard incision in a large series of gynecologic patients. Our modifications of the technique previously reported by Maylard and by Tollefson and Russell are presented in detail to provide the pelvic surgeon with increased confidence in use of the Maylard incision.

Patients and methods

One hundred seventy-five patients underwent pelvic-abdominal operations through a Maylard incision between March 1982 and September 1989. All procedures were performed by the house staff under our supervision at Fairfax Hospital (George Washington University Medical Center), Strong Memorial Hospital (University of Rochester), and the Medical College of Virginia. Only patients with an incision above the symphysis pubis were included in this study; we have previously reported our experience with the transverse periumbilical incision.[8] Study patients ranged in age from 21 to 80 years (mean, 46 years), and weights ranged from 44 to 180 kg (mean, 78 kg). The indications for operation are listed in Table I.

Thirty-three patients (19%) had preoperative external beam pelvic radiation therapy. Five patients had previous Pfannenstiel incisions, and two patients had large midline incisions with Marlex (C.R. Bard, Inc., North Billerica, Mass.) mesh repair of incisional hernias. Major medical problems (diabetes mellitus, cardiac disease, chronic obstructive pulmonary disease, and osteoporosis with vertebral fractures) were encountered in 20 patients (11.4%).

Surgical technique. A transverse skin incision is made 3 to 8 cm above the symphysis pubis and is carried down to the anterior rectus sheath. The exact location and length of the skin incision depend on the patient's age and weight, indication for operation, and previous abdominal or pelvic operation(s). The fascial sheath is then incised transversely to the lateral borders of the rectus muscles. By use of gentle finger dissection, the rectus muscle is teased away from the transversalis fascia, and a small right-angle retractor is placed beneath

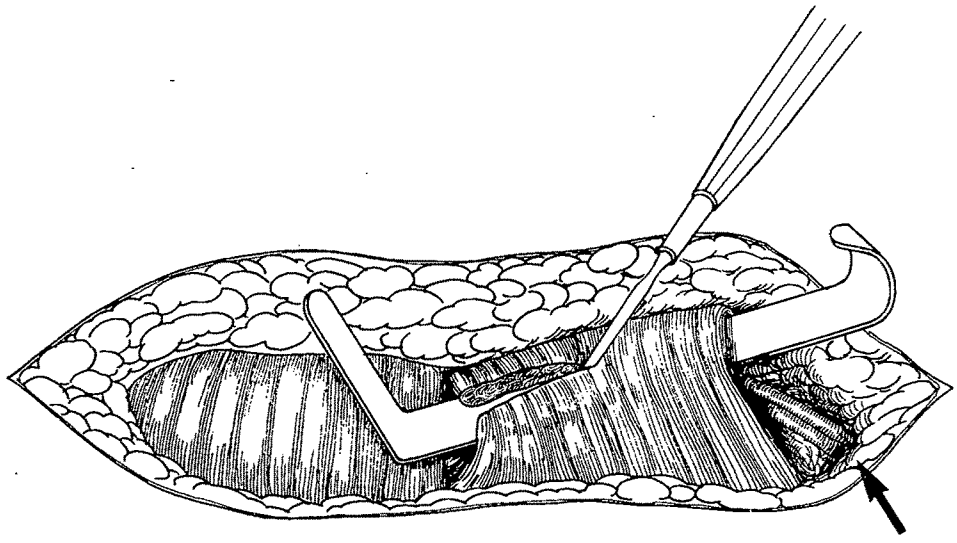

Fig. 1. A small right-angle retractor is used to elevate the rectus muscle and expose the inferior epigastric vessels *(arrow)*. Electrocautery is used to transect the rectus muscle.

it. The inferior epigastric vessels are found beneath the lateral one third of the muscle and are left within the transversalis fascia. The rectus muscle is then divided slowly by electrocautery (Fig. 1). Fine tonsil clamps are used to dissect the inferior epigastric bundle, and these vessels are tied with 2-0 silk. If the inferior epigastric vessels are readily visible and quite lateral in location, they may be ligated before the muscle is divided. The second rectus muscle is divided in a similar manner. Beginning laterally, the transversalis fascia and peritoneum are divided transversely with electrocautery or curved Mayo scissors.

A layered closure is readily accomplished. The peritoneum and transversalis fascia are closed with a continuous running 2-0 synthetic absorbable suture. A 10 mm flat Jackson-Pratt drain is placed across this suture line in the subfascial space, and exits through a separate stab incision (Fig. 2). It is removed when drainage is less than 40 ml per 24-hour period. The anterior rectus sheath is then closed with either interrupted or continuous suture of 0 synthetic absorbable or nonabsorbable material. No attempt is made to suture the retracted rectus muscles or include them in the fascial closure. The subcutaneous tissue is copiously irrigated with saline solution, and the skin edges are approximated with staples or a subcuticular suture.

Results

The surgical procedures performed in this series of 175 patients are listed in Table II. Thirty patients (17%) had a paraaortic node dissection as part of their operation.[9]

Table I. Preoperative indications for operation

Diagnosis	*No. of patients*
Cervical carcinoma-sarcoma	91
Endometrial carcinoma	58
Endometrial hyperplasia	4
Uterine leiomyomas–endometriosis	12
Benign tumors of ovary	4
Tuboovarian abscess	2
Hydrosalpinx*	1
Ovarian carcinoma	1
Vaginal clear cell carcinoma	1
Vulvar carcinoma	1
TOTAL	175

*Histologic examination confirmed fallopian tube carcinoma.

All patients had closed suction drainage of the subfascial space. The drain was left in place from 2 to 6 days (mean, 3.2 days) and collected from 24 to 350 ml fluid (mean, 120 ml) (one patient was excluded; see the paragraph on complications).

Fifty-six patients (32%) in this series received whole-pelvis radiation therapy. Thirty-three patients (19%) had preoperative radiation therapy, whereas 23 patients (13%) required postoperative radiation therapy.

Complications occurred in 12 patients (6.9%) and are summarized in Table III. Of the six patients with superficial wound infection, five were markedly obese (111 to 159 kg), three had insulin-dependent diabetes mellitus, and two had preoperative radiation therapy. The first four patients were treated with wound packing and long-term healing by secondary intention,

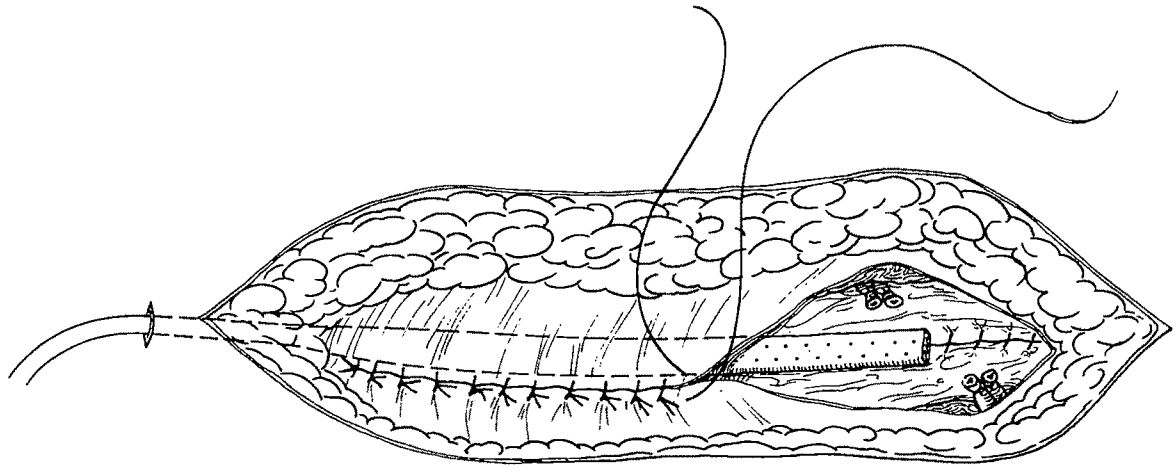

Fig. 2. The anterior fascia is closed over a 10 mm flat Jackson-Pratt drain.

Table II. Surgical procedures

Operation	*No. of patients*
Hysterectomy, with or without salpingo-oophorectomy	73
Hysterectomy, with or without salpingo-oophorectomy, pelvic lymphadenectomy	29
Radical hysterectomy, with or without salpingo-oophorectomy, pelvic lymphadenectomy*	59
Radical hysterectomy, paraaortic and pelvic lymphadenectomy, vaginectomy	1
Paraaortic and pelvic lymphadenectomy	6
Salpingo-oophorectomy	6
Reassessment laparotomy†	1
TOTAL	175

*Twenty-three of these patients also had paraaortic lymphadenectomy.

†Patient only agreed to operation through previous Pfannenstiel incision.

Table III. Postoperative complications

Complications	*No. of patients*
Superficial wound infection	6
Fasciitis	4
Subfascial hematoma	2

whereas the last two patients underwent rapid secondary closure with antibiotic administration.[10] Four patients had fasciitis that necessitated radical wound debridement and long-term healing by secondary intention. Three of these patients were obese (90, 91, and 160 kg) and had insulin-dependent diabetes mellitus. The two patients with subfascial hematoma had abnormal clotting factors but received minidose heparin. One patient was managed conservatively with prolonged catheter drainage (1090 ml over 11 days), whereas the second patient required evacuation of the hematoma on the second postoperative day.

Incisional hernia did not occur in any of the patients, including the four patients with fasciitis who required radical wound debridement of the anterior fascia. There were no deaths in this series.

Comment

The transverse abdominal incision has been used for over 150 years, and "... is based on sound anatomic, physiologic, and clinical principles."[2] When compared with a vertical incision, the following advantages of a transverse incision are readily noted: (1) a virtual absence of postoperative dehiscence[2, 6, 11, 12] and incisional hernia,[1, 2, 6, 12] (2) a significant decrease in pulmonary complications and postoperative discomfort,[2, 4, 6, 13] and (3) excellent cosmetic results.[1, 4] Conversely, limited access to the pelvis and upper abdomen has always been the primary disadvantage of the Pfannenstiel incision, the most popular transverse incision used by pelvic surgeons. Fortunately, Ernest Maylard and his proponents have resolved this dilemma with the transverse muscle-splitting incision. Although initial concern was raised with regard to the healing of the abdominal wall with the Maylard incision, numerous clinical and animal studies[1, 3, 4, 6, 12, 13] have shown that fibroblastic proliferation creates a new transverse band of fibrous tissue (linea transversa) where the muscle is cut.

Our series of 175 patients illustrates the adaptability of the Maylard incision depending on the indications for operation, the anticipated surgical procedure, the patient's age, weight, and previous surgical history, and known medical problems. For example, we often use

the Maylard incision in adolescents and young women with ovarian neoplasms when the index of suspicion for malignancy is low. Eighty-seven percent of all procedures in this series were performed for pelvic malignancies. We concur with Mann et al.[7] that the Maylard incision is preferred for radical hysterectomy. The excellent exposure obtained with the Maylard incision is emphasized by the fact that 95 patients (54%) underwent pelvic lymphadenectomy, and 30 patients (17%) also had paraaortic lymph node dissection.

Two modifications in the technique popularized by Maylard and Tollefson and Russell are suggested. First, the rich anastomotic blood supply to the rectus muscle allows the inferior epigastric vessels to be routinely ligated. This will minimize tearing of these vessels during lateral retraction and maximize the incision through the transversalis fascia and peritoneum. Ligation of these vessels was not described by Maylard,[1] and was performed in only one third of the patients of Tollefson and Russell.[6] Second, a closed suction drain is placed in the subfascial space in all patients. Our average collection of 120 ml drainage supports its routine use to minimize hematoma or seroma formation. This is in contrast to the series by Mann et al.[7] in which drains were used in only 44% of patients.

Our complication rate of 6.9% is comparable with the 4% to 5% rate reported by Mann et al.[7] and Tollefson and Russell.[6] Marked obesity and diabetes are recognized factors in poor wound healing and were present in the majority of the 10 patients in whom superficial wound infection or fasciitis developed. We believe that the two cases of subfascial hematoma were probably preventable if strict attention had been paid to coagulation values.

Femoral neuropathy and other nerve injuries have been reported in patients with low transverse incisions.[14, 15] Neither these injuries nor incisional hernia and dehiscence were encountered in this series.

There are few disadvantages to the Maylard incision. Although a few more minutes are required for transection of the muscles and ligation of the inferior epigastric vessels,[16] we agree with Christopherson[12] that the Maylard incision should not be used if prompt visualization of the abdomen or pelvis is a critical factor. Second, a vertical incision is preferred when optimal exposure of the upper abdomen is required, for example, for exploration for ovarian carcinoma or other advanced pelvic malignancies. Conversely, we disagree with the conclusion by Mann et al.[7] that the Maylard incision should not be used in a pelvis that has been treated by radiation. Fifty-six patients in this series received pelvic radiation therapy, and only two of these were among the 10 patients in whom wound complications developed. Our data show that preoperative radiation therapy is not a contraindication for use of the Maylard incision, and that wound healing is not adversely affected by postoperative radiation therapy.

As shown in this series of 175 patients, the transverse muscle-splitting incision is adaptable to many different clinical situations. It is easily learned, well accepted by patients, and has a low complication rate. When optimal pelvic exposure is necessary, and speed of entry and access to the upper abdomen are not critical factors, the Maylard incision is our preferred surgical incision.

Ultrasonographic diagnosis of a large placental intervillous thrombosis associated with elevated maternal serum α-fetoprotein level

Eric Jauniaux, MD,* Donald Gibb, MD, Gonzalo Moscoso, MD, and Stuart Campbell, FRCOG

London, England

A placental lesion associated with elevated maternal serum α-fetoprotein level and a positive Kleihauer-Betke test is reported. Serial ultrasonograms showed a progressive increase in the echogenicity of the lesion that corresponded to a large intervillous thrombosis after delivery. This case illustrates the importance of detailed ultrasonographic and pathologic placental investigations in pregnancies with unexplained elevated levels of α-fetoprotein. (Am J Obstet Gynecol 1990;163:1558-60.)

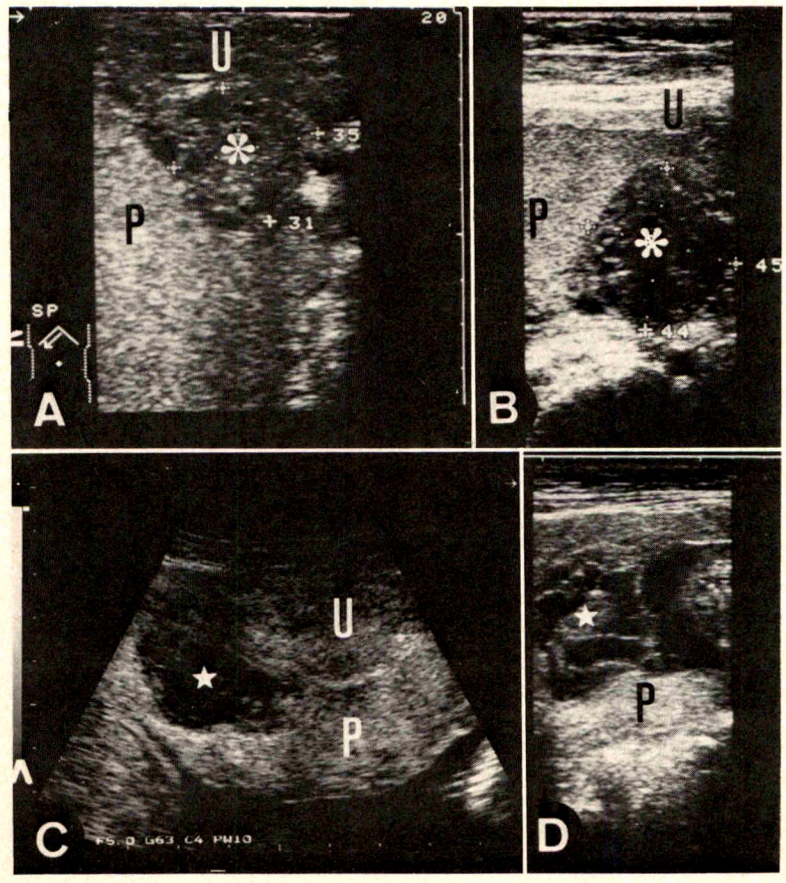

Fig. 1. Composite compound scan of uterus *(U)* and placenta *(P)* shows heterogeneous and hypoechoic placental lesion *(asterisk)* at 17 **(A)** and 22 **(B)** weeks' gestation. For comparison, **C,** a retroplacental hematoma *(star)* at 32 weeks, 2 weeks after an invasive procedure, and **D,** a recent marginal hematoma *(star)* at 18 weeks.

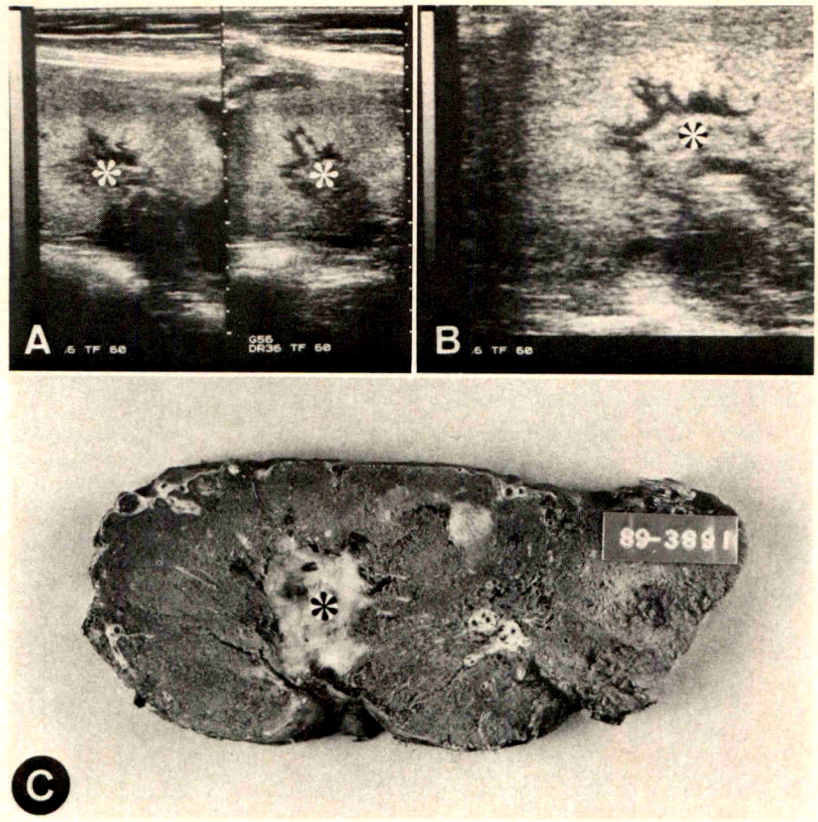

Fig. 2. A, Transverse and longitudinal ultrasonogram of placenta shows placental lesion at 35 weeks *(asterisk)*. **B,** Lesion is isoechoic and surrounded by sonolucent spaces containing turbulent blood flow on real-time imaging. **C,** Macroscopic view of lesion *(asterisk)* corresponds histologically to an old intervillous thrombosis.

Maternal serum α-fetoprotein (AFP) concentrations are routinely performed between 16 and 20 weeks' gestation as a screening test for different fetal anomalies. Elevated AFP levels can also be found in association with well-defined placental lesions without associated fetal anomalies such as chorioangiomas[1] or in combined fetoplacental pathologic conditions such as triploidy.[2] We described an unusual placental lesion that ultrasonographically resembled a hematoma or a chorioangioma and was associated with an elevated maternal serum AFP level.

Case report

A 29-year-old healthy nonsmoking primigravid woman was referred because of elevated maternal serum AFP levels (4.5 and 4.8 multiples of the median). At 18 weeks' gestation ultrasonography showed a singleton and anatomically normal fetus with measurements consistent with the estimated gestation. The placenta was fundal and contained a 3.1 × 3.5 cm heterogeneous and hypoechoic lesion (Fig. 1, *A*). A hematoma or a chorioangioma was suspected and ultrasonographic follow-up of the pregnancy was started. At that time a Kleihauer-Betke test had positive results.

At 22 weeks the lesion was larger, well demarcated (Fig. 1, *B*), and contained turbulent blood flow on real-time scanning. Weak flow velocity waveforms with maternal characteristics were detected at the level of the lesion on color Doppler flow imaging. These findings were compared with the ultrasonographic features of a retroplacental hematoma and of a subchorionic (marginal) hematoma, both of which were subsequently confirmed after delivery. In these two cases no blood flow was found in the lesion. These lesions were hyperechoic to isoechoic in the acute stage (Fig. 1, *D*) and hypoechoic to sonolucent within 2 weeks (Fig. 1, *C*).

At 29 weeks slow fetal growth (5th percentile) and reduced amniotic fluid volume were noted. Fetal and uteroplacental Doppler studies were within our normal ranges. The placental lesion was homogeneous, isoechoic (Fig. 2, *A*), and surrounded by small sonolucent spaces (Fig. 2, *B*) that contained turbulent flow. Similar antepartum features were observed until term. Because of breech presentation and poor fetal growth, the patient was delivered by cesarean section of a healthy female infant weighing 2230 gm. The postpartum course was uneventful.

The placenta weighed 410 gm. Examination of the slices showed a white lesion of 3 × 3 × 4 cm, composed histologically of laminated fibrin surrounded by several groups of infarcted villi (Fig. 2, *C*). There was no evidence of a retroplacental hematoma.

Comment

Ultrasonographic investigation of the placenta in patients with elevated maternal serum AFP levels has shown a high incidence of retroplacental or subchorionic placental hemorrhage.[1] However, in this study serial ultrasonographic examination and pathologic correlation were not performed.

The placenta is a dynamic organ. As demonstrated in this case, the ultrasonographic appearances are dependent on gestational age and the evolution of the lesion. At the time of AFP screening, the lesion was hypoechoic and contained turbulent blood flow. Six weeks later the lesion was more echogenic. In contrast, resolving hematomas become sonolucent and do not demonstrate blood flow. A placental chorioangioma was also unlikely because color Doppler flow studies of the lesion only detected maternal flow velocity waveforms.

The association of an increased maternal serum AFP level with a positive Kleihauer-Betke test is suggestive of a breakdown of the placental barrier[2] and should lead to detailed assessment of placental appearance.

Elevated maternal serum AFP levels, combined with abnormal placental ultrasonographic features, may be an early indication of subsequent perinatal complications, particularly fetal intrauterine growth retardation. Further placental ultrasonographic and pathologic investigations in a prospective manner are needed to validate the relationship between the development of placental lesion, elevated maternal serum AFP, and fetal outcome.

Direct ultrasonographic measurement of fetal lung length in normal pregnancies and pregnancies complicated by prolonged rupture of membranes

Alistair B. Roberts, MD, and Jennifer M. Mitchell, DMU
Auckland, New Zealand

Fetal lung length was measured directly with ultrasonography in 20 patients with prolonged rupture of membranes, commencing before 25 weeks' gestation. Measurements were made weekly and compared with data collected from 310 normal pregnancies. Measurement of fetal lung length by ultrasonography was a good predictor of pulmonary hypoplasia, predicting >90% of cases. There was a good correlation between lung size assessed by the last ultrasonographic examination and lung weight postmortem ($r = 0.783$, $p < 0.05$). Lung length measurements were superior to fetal chest circumference measurements in the identification of pulmonary hypoplasia. There was a significant negative association between the amount of amniotic fluid and pulmonary hypoplasia ($p < 0.05$). There were fetuses with pulmonary hypoplasia that had respiratory movements seen at the majority of ultrasonographic examinations. (AM J OBSTET GYNECOL 1990;163:1560-6.)

Fetal pulmonary hypoplasia is a significant contributor to neonatal death.[1] It occurs as a consequence of prolonged rupture of membranes,[2] renal agenesis, diaphragmatic hernia, pleural effusions, and skeletal dysplasias.[3-5] Antepartum prediction of pulmonary hypoplasia has been elusive.[6]

Ultrasonography has contributed by use of mea-

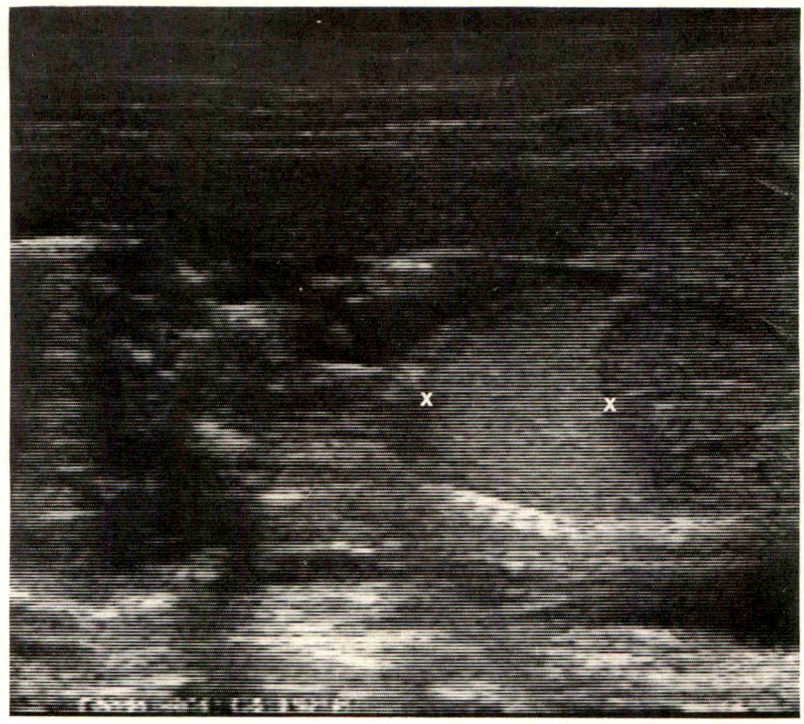

Fig. 1. Ultrasonogram of the fetal lung in sagittal section with *crosses* indicating method of measurement from base of lung at dome of diaphragm to apex of lung adjacent to clavicle.

surements of chest circumference and area,[7] either directly or by comparison with other fetal measurements,[8, 9] but no direct measurements of lung size have been reported. Attempts have been made to predict hypoplasia by use of fetal breathing movements but the results have been contradictory.[10, 11]

In this study we aimed to measure the fetal lung directly with ultrasonography. We elected to measure fetal lung length and use this as an index of lung size. We first studied a group of patients with normal pregnancies and then a group of patients with prolonged rupture of membranes. In the latter group recordings were also made of liquor volume and breathing movements.

Patients and methods

A total of 310 uncomplicated pregnancies between 12 and 40 weeks' gestation were studied. All patients had regular menstrual periods and a confirmatory ultrasonographic examination before 20 weeks' gestation. They were all singleton pregnancies and were delivered within 2 weeks of the expected date of delivery. Growth-retarded infants below the 5th percentile and macrosomic infants above the 95th percentile were excluded (size was compared with nomograms from National Women's Hospital). The data collected were cross-sectional with one measurement per patient. All data were collected as part of normal ultrasonographic examinations requested by each patient's physician. Examinations were performed with Toshiba real-time ultrasonographic equipment. Measurements were made of fetal lung length and fetal chest circumference. Great care was taken to ensure that there were adequate data points at each stage of gestation.

The length of the fetal lung was measured by taking a sagittal section through the fetal chest (Fig. 1). The lung was measured from the tip of the apex to the base of the lung on the dome of the diaphragm during fetal apnea. Data collected from the left lung in an initial pilot study on 10 patients showed no differences between the left and right lungs. Care was taken to ensure that the apex was reached and also to identify the top of the diaphragm because the diaphragmatic insertions are significantly lower. The clavicle was used as a marker to ensure that the apex was reached. The decision to use the left lung was an arbitrary one to ensure that the same lung was always measured. The left lung was always measured including the cases with ruptured membranes. We have since realized that the right lung is easier to visualize because there is less encroachment from the heart.

Chest circumference was measured in a plane at right angles to the fetal spine with atrioventricular valves as the marker. This approximates a four-chamber view of the fetal heart but was slightly rotated to ensure that the section was at right angles to the spine.

*Number of weeks that membranes were ruptured before delivery.
†Gestational age when last ultrasonographic examination was performed.
‡Lung length measurement at last ultrasonographic examination.
§Ratio of examinations during which breathing was observed/total number of examinations.
‖Mean amniotic fluid pocket size over all examinations.

Patients with ruptured membranes before 25 weeks' gestation were also studied. Drainage of amniotic fluid was confirmed clinically by examination and fluid continued to drain until delivery in all cases. In no case was there clinical evidence of amniotic infection; there were no significant contractions until just before delivery. No tocolytic agent was given in any case, and all patients elected conservative treatment. They all had ruptured membranes of >1 weeks' gestation and full details are given in Table I. Fetal lung measurements were made once a week (left lung), and estimates were made of the amount of amniotic fluid and whether fetal breathing movements were present. Fetal breathing was defined as any chest wall or diaphragmatic movement that had the appearance of breathing and was not associated with other fetal movements. At least two breaths within 6 seconds had to occur before breathing was recorded. One isolated breath was not considered "breathing." The number of examinations during which breathing was seen were recorded. The mean examination time was approximately 20 minutes. The amount of amniotic fluid was assessed by measurement of the largest clear vertical pocket of fluid on each occasion. The mean size of these pockets was calculated for all examinations.

If fetal or neonatal death occurred only patients with postmortem evidence of lung size or strong clinical and radiologic evidence were included. The pathologic diagnosis of pulmonary hypoplasia was made with the ratio of lung weight/body weight. Ratios <0.012 were accepted as abnormal.[12]

Scattergrams of lung length and chest circumference against gestational age were drawn and regression analysis used with estimation of the regression line with 95% prediction intervals.

Reproducibility of the lung length measurement and chest circumference was assessed between different observers measuring "blind" to each other's results, and for the same observer. Interobserver differences of lung length were <8% for 95% of the time. Intraobserver differences were <6%. Chest circumference values were 12% and 8% for inter- and intraobserver differences, respectively. These were not influenced significantly by gestational age. Reproducibility studies were not performed separately in patients with ruptured membranes. Statistical analysis of data from patients with ruptured membranes was made with the Epistat (Epistat Services, Richardson, Tex.) computer program with Fisher's exact test, Pearson's correlation coefficent, and multiple logistic regression analysis. Regression equations for lung length and chest circumference data were analyzed and produced by the Mathematics Department at Auckland University.

Results

Nomograms for fetal lung length and chest circumference with respect to gestational age were produced. The regression equation for lung length was

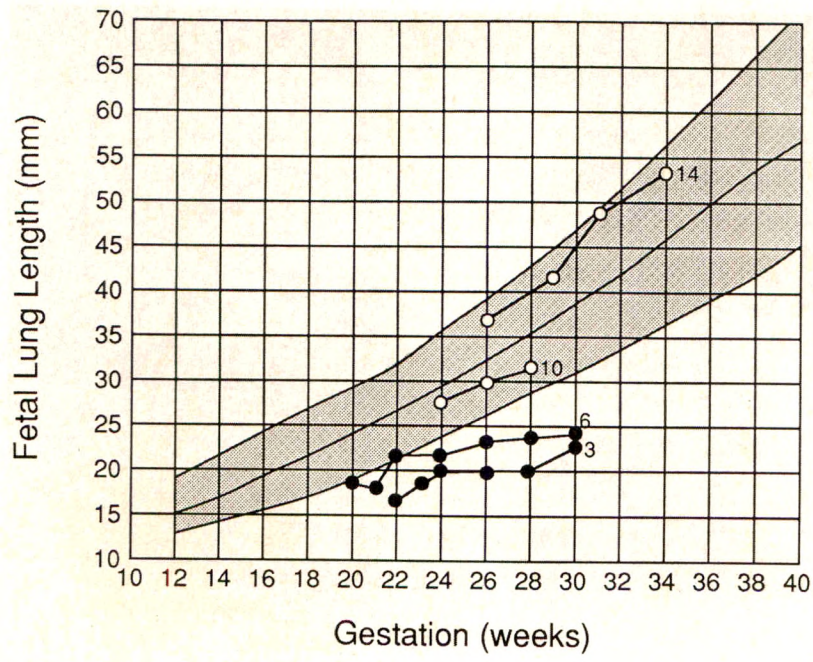

Fig. 3. Normal graph for lung length with *superimposed circles* representing patients with ruptured membranes of >3 weeks. *Open circles* represent patients in whom fetus and neonate had normally grown lungs; *closed circles* represent neonates with pulmonary hypoplasia.

as follows: Log lung length = 1.7528 + 0.0802 × gestational age − 0.00058 × gestational age^2.

The scattergram of lung length against gestational age is shown in Fig. 2.

A total of 20 patients with prolonged ruptured membranes were eventually included in the study. All had ruptured membranes of ≥1 week with a range of 1 to 12 weeks (mean, 3.9 weeks). Membranes ruptured between 18 and 24 weeks' gestation (mean, 22.2 weeks). There were six survivors. Of the 14 deaths 12 had

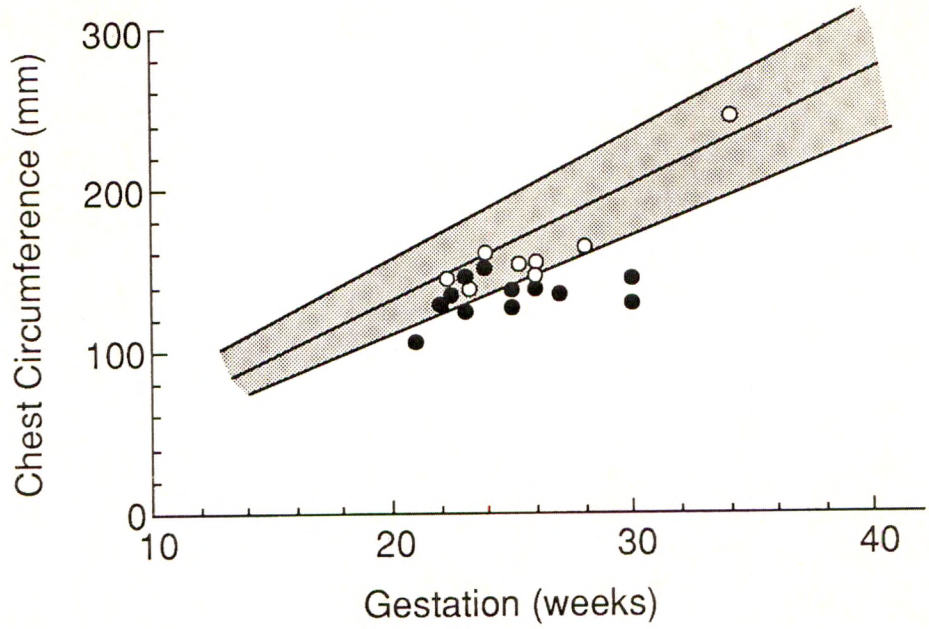

Fig. 4. Mean + 95% prediction intervals for fetal chest circumference plotted against gestational age. *Superimposed circles* represent measurements made in patients with ruptured membranes. *Open circles* represent normal lungs; *closed circles* represent pulmonary hypoplasia.

evidence of pulmonary hypoplasia (10 postmortem and two clinical and radiologic) (Table I).

There was a significant association between ultrasonographic measurement of lung length and pulmonary hypoplasia ($p < 0.001$). Of the 12 fetuses with pulmonary hypoplasia, 11 had a last ultrasonographic measurement of lung length that was outside the 95% prediction intervals (Fig. 2). The results of lung growth in four fetuses with ruptured membranes >4 weeks are plotted in Fig. 3. Lung size by last ultrasonographic examination correlated well with lung weight postmortem ($r = 0.783$, $p < 0.05$).

Chest circumference measurements were below the 95% prediction intervals in eight of the 12 fetuses with pulmonary hypoplasia (Fig. 4).

Average size of amniotic fluid pockets ranged from 0 to 3.7 cm, with a mean of 1.05. Fetuses with amniotic fluid <1.5 cm were more likely to have lung hypoplasia ($p < 0.05$). There were four fetuses with no amniotic fluid seen and in all instances the fetuses had pulmonary hypoplasia. The four fetuses with pockets of fluid >1.5 cm had normal lung growth (Table I).

Breathing movements were observed in 63% of examinations. There was no significant association between the presence or absence of breathing and lung hypoplasia. However, fetuses that were breathing during the majority of examinations (>50%) were significantly more likely to have normal lung growth ($p > 0.05$). If membranes ruptured before 22 weeks' gestation then pulmonary hypoplasia was more likely ($p < 0.05$).

In 10 of 12 fetuses with pulmonary hypoplasia the membranes were ruptured for ≥3 weeks, but the association between duration of ruptured membranes and pulmonary hypoplasia did not reach statistical significance.

Multiple logistic regression analysis was used with the computer selecting the variables that contribute to the prediction of pulmonary hypoplasia. A significance level of 0.05 was chosen for inclusion. Lung length, amount of amniotic fluid, gestational age at rupture, and average time spent breathing were selected to enter the regression in that order, with p values of 0.000002, 0.0002, 0.001, 0.02, respectively. Lung length alone accounted for 84.3% of the log likelihood. The addition of either of the other variables could be used to correctly classify 100% of cases. For example a model with lung length and amount of amniotic fluid had coefficients of −1.510 and −45.982, respectively, with the regression accounting for 100% of the log likelihood.

Comment

The measurement of lung length seems to be useful in the management of the patient with ruptured membranes, correctly identifying >90% of the patients at risk of pulmonary hypoplasia. With the addition of amniotic fluid volume it was possible to correctly classify 100%. Lung length measurement in our hands was a better predictor of pulmonary hypoplasia than was chest circumference. The measurement is reproducible with high-resolution ultrasonographic equipment and experienced observers. There was a good correlation

between lung length measured by ultrasonography and lung weight postmortem. The normal values can also be applied to situations of diaphragmatic hernia, pleural effusion, and hydrops to accurately measure lung size. There seems to be reduction in lung size after drainage of liquor in some cases but in only one case (patient No. 18, Table I) was the lung length below 2 SDs within 1 week of rupture, and the diagnosis of pulmonary hypoplasia was confirmed postmortem, suggesting the possibility of more prolonged pathology than was thought. These measurements were made on the left lung and should be applied to it. However, we found no significant difference between lungs in length, and if the left lung is difficult to measure then measurements from the right lung can be used.

The next most useful predictor of pulmonary hypoplasia was the amount of amniotic fluid. In all cases with amniotic fluid pockets averaging >1.5 cm the lungs grew normally. If no amniotic fluid was seen there was pulmonary hypoplasia in four of four fetuses (Table I). This contrasts with recent data[13] in a study of 88 infants with ruptured membranes of >7 days in which no correlation was found between the degree of oligohydramnios and pulmonary hypoplasia. In that study, however, the data were retrospective and the ultrasonographic scans performed by different centers with the analysis in some instances being made from ultrasonographic reports. Amounts of amniotic fluid are difficult to assess and considerable experience is required. All scans in our study were performed by the authors. In the study by Rotschild et al.[13] only the last ultrasonographic study was analyzed, whereas we averaged the amount of amniotic fluid from all examinations. Nevertheless Rotschild et al.[13] did note that 12 of 14 infants with pulmonary hypoplasia had moderate or severe oligohydramnios (86%) at the last ultrasonographic examination.

If the membranes ruptured before 22 weeks' gestation all fetuses or neonates died and all had pulmonary hypoplasia.

Breathing movement analysis is more complex. In this study we recorded breathing as positive if more than two breaths were noted together. The studies were performed during an ultrasonographic examination and were not accurately quantified. Therefore care should be taken in making inferences from the observations. We can confirm,[11] however, that pulmonary hypoplasia does develop in some fetuses with frequently observed breathing movements (patient No. 6, Table I). This does not contradict the findings of Blott et al.,[10] inasmuch as they defined breathing as only present if the episode lasted 60 seconds, whereas in our study many of the episodes were of shorter duration. The absence of breathing movements was associated with hypoplasia in five of six cases. Certainly persistent absence of breathing movements over several weeks is a poor prognostic sign. However, the mere presence of breathing movements cannot always be taken as a good prognostic sign. This study did not measure the duration of breathing movements or the degree of diaphragmatic excursion and these may be more useful discriminants.

The interrelationships between these various factors and lung growth are not clear, but if absence of amniotic fluid or breathing leads to pulmonary hypoplasia then it should take time. This group of patients suggests that the membranes must be ruptured for ≥3 weeks before significant growth problems occur. However, there were two exceptions to this rule with pulmonary hypoplasia developing in patient No. 5 after 2 weeks of membrane rupture and in patient No. 18 after only 1 week. Perhaps there was in fact more prolonged membrane rupture that was not detected or oligohydramnios for other reasons. Or possibly even short periods of oligohydramnios can lead to pulmonary hypoplasia at critical periods of development.

The patients with ruptured membranes of >1 month are shown in Fig. 3 and illustrate some of the difficulties in forming hypotheses. Patient No. 14 had definite ruptured membranes with continuous leakage but always had reasonable amniotic fluid on ultrasonographic examination, which probably accounts for the normal lung growth. Patient No. 10 had good amniotic pockets of >1.6 cm for the first 3 weeks and then no amniotic fluid for the last week. Patient No. 6 had amniotic fluid pockets of <1.5 cm for the first 4 weeks but later had pockets of >2 cm; patient No. 3 similarly had less amniotic fluid for the first few weeks and then more. In all instances breathing movements were detected on 50% of the examinations or more. In both patients with pulmonary hypoplasia the membrane rupture occurred before 22 weeks' gestation and this seems to be the most important prognostic indicator.

Grateful thanks to Professor A. Scott of the Mathematics Department, Auckland University, for help with the regression equations and analysis of the data.

Color flow Doppler—A useful instrument in the diagnosis of vasa previa

James A. Harding, MD, David F. Lewis, MD, Carol A. Major, MD, Michael Crade, MD, Jagdish Patel, MD, and Michael P. Nageotte, MD

Long Beach and Orange, California

Vasa previa is associated with an increased perinatal mortality rate and rarely is diagnosed in the antepartum period. We present a case in which vasa previa was correctly diagnosed by use of color flow Doppler imaging. This modality is a valuable adjunct in the evaluation of patients suspected to have vasa previa. (Am J Obstet Gynecol 1990;163:1566-8.)

Key words: Vasa previa, Doppler, color flow Doppler, prenatal diagnosis

Vasa previa is a rare condition in which a placental blood vessel crosses an area of the amnion overlying the cervical os. When this vessel is severed, the fetus can exsanguinate in a matter of minutes; thus the condition is associated with a high fetal mortality rate. The antenatal diagnosis of vasa previa is rarely reported. Ultrasonography and Doppler imaging have been used to diagnose vasa previa in the antenatal period.[1] We report the correct diagnosis of vasa previa by means of color flow Doppler imaging in a patient during the antenatal period.

Case report

A patient (gravida 3, para 1-0-1-1) who was Rh-positive was admitted at a gestational age of 24⅐ weeks with vaginal bleeding. The vaginal bleeding, estimated at 1000 ml, ceased after admission. The patient refused all blood products for religious reasons. Ultrasonography revealed a left posterior marginal placenta previa with a right anterior secondary lobe thought to be succenturiate. Doppler flow evaluation of the region between the placental beds revealed an area of pulsatile flow. Color flow Doppler imaging delineated a vessel coursing across the cervical os with pulsations corresponding to the fetal heart rate (Fig. 1).

Because of the concern over fetal risk of acute blood loss with spontaneous rupture of membranes, a controlled delivery by cesarean section was planned. Amniocentesis was performed at 34 weeks' gestation and fetal pulmonary maturity was established.

At delivery a normal appearing female with a birth weight of 1975 gm and Apgar scores of 8 and 9 at 1 and 5 minutes, respectively, was delivered without interrupting the placental integrity. Initial hematocrit of the baby was 58%. An intact large-bore vessel was identified coursing across the cervical os from the marginal left-posterior previa to the right-anterior succenturiate lobe (Fig. 2).

The postoperative course was uncomplicated, and the patient was discharged home with her infant on the sixth postoperative day.

Comment

Vasa previa is associated with a high fetal mortality rate. The incidence is approximated to be one in 2000 to 3000 deliveries.[2] Diagnosis of vasa previa has always remained elusive to the clinician. In 1979 Pent[3] outlined the strategies for diagnosing vasa previa at that time. His discussions focused on the diagnosis of vasa previa during the intrapartum period, which involved methods to identify fetal bleeding after the vessel had ruptured. In his report he raised the issue of the possible

use of ultrasonography for the antenatal diagnosis of vasa previa, but thought that the technology at that time could not clearly delineate vessels so deep in the pelvis. In 1987 Gianopoulos et al.[1] reviewed a case report of a succenturiate lobe with a vasa previa detected by ultrasonography and Doppler flow imaging to accurately identify the condition before delivery.

Advancements in Doppler technology include the recent evolution of color flow Doppler. Color flow Doppler imaging use computer-generated colored imprints linked to Doppler signals that correlate with directional vascular flows. The benefits of this tool include identification of smaller vessel flows that initially may escape the scanning M-mode resolutions and standard Doppler techniques.

Maintaining a high index of suspicion is the key to diagnosis of vasa previa. In this respect, the patient with identified ultrasonographic findings at risk for a vasa previa (such as a low-lying to marginal placenta previa, velamentous insertion of the cord, succenturiate lobes of the placenta, or multiple gestations) should warrant color flow Doppler evaluation of the cervical region to rule out a vasa previa. Although the precision of this technique needs further evaluation, it holds promise for improvements in the detection of this highly fatal condition.

Reliability of ultrasonographic formulary in the prediction of fetal weight and survival of very-low-birth-weight infants

Marlin D. Mills, MD,[a] Michael P. Nageotte, MD,[b] John P. Elliott, MD,[a] Michael Crade, MD,[b] and Wendy Dorchester, MPH[b]

Phoenix, Arizona, and Long Beach, California

Antenatal management of very-low-birth-weight infants often requires difficult obstetric decisions. This study was designed to evaluate the predictive value for neonatal outcome of antenatally acquired estimation of gestational age and ultrasonographically estimated fetal weight or a combination of both in very-low-birth-weight infants. Sixty-seven fetuses with estimated gestational ages between 22⁶/₇ and 28⁶/₇ weeks were studied ultrasonographically to estimate fetal weight. A comparison of accuracy of estimated fetal weight with actual birth weight showed good correlation ($r = 0.93$). Neonatal outcome of these infants was analyzed by estimated gestational age and estimated fetal weight. Estimated gestational age and estimated fetal weight >25 weeks and >750 gm were associated with 50% survival, respectively. However, when both of these conditions were met survival reached 85%. This information may be useful to guide antepartum management decisions in this very-low-birth-weight group. (Am J Obstet Gynecol 1990;163:1568-74.)

Delivery of a premature infant with a birth weight <1500 gm occurs in approximately 3.9% of all pregnancies. However, this group accounts for 75% of the total perinatal mortality.[1] Over the last several years, significantly better long-term survival statistics of infants born at earlier gestational ages and lower birth weights have been reported.[2,3] In addition to improved neonatal technologies and expertise, there are other

factors beyond the control of the neonatal team that also appear to have significant influence on the outcome of these infants. These include actual birth weight, estimated gestational age, abnormal fetal growth patterns, fetal acidosis, mode of delivery, and location of delivery.[4] The obstetrician's perception of potential viability influences these factors and determines whether aggressive obstetric management, including transfer to a regional perinatal center, or the performance of a cesarean delivery for fetal indications will be used.

Perinatal mortality has been shown to be related to both gestational age and actual birth weight, although each may have an independent effect.[5] Actual birth weight statistics have limited usefulness to the obstetrician, however, because the actual birth weight is unknown before delivery and cannot be used to guide obstetric management. Clinically, fetal weight is often underestimated when compared with actual birth weight. When this occurs, aggressive obstetric intervention, which would otherwise be indicated, is often withheld, resulting in potentially worsened perinatal outcome.[6] Early attempts to antenatally predict actual birth weight by ultrasonographic measurements of various fetal structures and to thereby improve clinical estimated fetal weight were based on studies of infants with actual birth weights >1000 gm.[7,8] Formulas to estimate fetal weight may vary in accuracy at different weight ranges and therefore need to be evaluated for the very-low-birth-weight group.[9]

The usefulness of the antenatal estimation of gestational age is limited because of the frequency with which accurate menstrual dating information is unavailable. Neonatal estimate of gestational age is not accurate enough in the very-low-birth-weight group to allow development of survival tables useful for antenatal management.[10] Ultrasonographic estimation of gestational age also has been shown to have a significantly large range of error and thus limits the sole application of this technique for prospective management of these patients.[11]

The focus of this study was to determine the accuracy of ultrasonographically estimated fetal weight with available formulas to predict actual birth weight in the very-low-birth-weight fetuses. The following question was then asked: could this estimate of fetal weight predict neonatal outcome when compared with or combined with the estimated gestational age?

Material and methods

Women admitted to the labor and delivery suite at Long Beach Women's Hospital from Oct. 1, 1983, through May 30, 1985, with a diagnosis of threatened preterm delivery and a gestational age between 22⅞ weeks and 28⅞ weeks were initially evaluated. Threatened preterm delivery was defined as one of the following: a diagnosis of preterm labor treated with intravenous tocolysis, with or without cervical change; preterm premature rupture of membranes; or a maternal complication necessitating delivery in the above gestational age range. Gestational age was determined by calculating from the patient's last menstrual period, by early physical examination or early examination by ultrasonography, or by ultrasonographic measurements of the fetus taken during the current hospital admission if this was the only information available. Neonatal assessment of gestational age was not used for analysis because of its inaccuracy in this age group.

All patients had an obstetric ultrasonographic examination at the time of admission. The equipment used for this examination was an Acuson real-time ultrasonographic scanner, an ATL-3000-1C real-time ultrasonographic scanner, and a Toshiba SAL-20 portable real-time ultrasonographic scanner. All images were recorded in multiimage format on radiographic transparency film. Fetal ultrasonographic measurements for estimation of gestational age and estimation of fetal weight included biparietal diameter, head circumference, femur length, and abdominal circumference. Biparietal diameter was measured according to the method described by Campbell and Thoms[12] and further defined by Hadlock et al.[13] The occipitofrontal diameter and head circumference were determined from measurements made at this level. Head circumference was determined by the method described by Hadlock et al.[14] using a transverse and longitudinal diameter. The femur length was measured as described by Hadlock et al.[15] Abdominal circumference was calculated by two methods. First, a hand-held map reader was used to trace the abdominal circumference on the radiographic transparency. The second method used transverse diameters as described by Campbell and Thoms.[12] Each method of measuring abdominal circumference was then compared for accuracy. Additional information obtained from the ultrasonographic examination included amniotic fluid volume and fetal presentation. The cephalic index was calculated by the method described by Hadlock et al.[13] with a normal range (±2 SDs) of 70% to 86%. All parameters were analyzed for effect on the accuracy of estimated fetal weight prediction.

Fetal weight was estimated according to two previously published formulas.[7,8] Each formula was calculated with the abdominal circumference measured by the two methods described (Shepard I, Warsof I—map reader; Shepard II, Warsof II—transverse diameters). These estimates were then compared with actual birth weight for prediction accuracy.

The ultrasonographically estimated fetal weight was blinded from the managing obstetrician before delivery. Management decisions were based solely on the

Table I. Comparisons of actual birth weight and calculated values for all infants

	Birth weight (gm, mean ± SD)	*Correlation with actual birth weight (r)*
Actual birth weight	792.7 ± 223.6	1.0000
Shepard EFW I	765.7 ± 219.6	0.9011
Warsof EFW I	807.6 ± 233.0	0.9010
Shepard EFW II	793.6 ± 242.2	0.9309
Warsof EFW II	839.8 ± 258.2	0.9287

EFW, Estimated fetal weight. Comparison among five correlation coefficients shows no statistical significant differences.

estimated gestational age. Cesarean delivery was performed for fetal indication (i.e., malpresentation, or fetal distress) only if the estimated gestational age was considered to be ≥26⅞ weeks. Although cesarean section was not performed for infants with an estimated gestational age <26⅞ weeks, these patients were still managed with care to provide a controlled vaginal delivery. Continuous external fetal monitoring was used. Patients were positioned to reduce the occurrence of variable decelerations as a result of cord compression. Oxygen was provided to the mothers if there was an abnormal fetal heart rate pattern, and hydration was used to improve uterine perfusion.

Actual birth weight was recorded after delivery. Neonatal outcome was evaluated for mortality, length of hospital stay, incidence of respiratory distress syndrome, retrolental fibroplasia, bronchopulmonary dysplasia, sepsis, necrotizing enterocolitis, intraventricular hemorrhage, seizures, and patent ductus arteriosus necessitating surgical ligation. The incidence of these complications was then correlated with estimated gestational age, actual birth weight, and estimated fetal weight. An analysis of neonatal mortality data at the neonatal intensive care unit at Long Beach Women's Hospital, as well as data from this study, showed that survival >50% occurred in the 700 to 800 gm actual-birth-weight group. A birth weight of 750 gm was chosen to represent this group. Outcome was then analyzed for birth weights above and below this weight and compared with ultrasonography-estimated fetal weight, and estimated gestational age for survival and morbidity.

The data were subjected to statistical analysis by means of χ^2 with Fisher's exact test and Yates' correction where appropriate.

Results

Ninety-eight patients were admitted and subsequently delivered during the study period with a gestational age between 22⅞ and 28⅞ weeks. Thirty-one patients were excluded from analysis because of ultrasonographic examination >72 hours from delivery, absent or inadequate ultrasonographic examination, intrauterine growth retardation diagnosed before delivery, congenital anomalies diagnosed before delivery, or multiple gestation. A total of 67 patients were available for analysis. Gestational age was determined by last menstrual period with confirming ultrasonographic examinations in 60% of the patients, early ultrasonographic examination with follow-up examination in 31%, and late ultrasonographic examination only in 9% of patients. There was no difference in outcome among these three groups. The maternal factors responsible for preterm delivery included premature rupture of membranes, premature labor, severe preeclampsia, abruptio placentae, chorioamnionitis, and incompetent cervix. Maternal diagnosis did not influence neonatal outcome when corrected for gestational age and birth weight, although some groups were too small for adequate statistical analysis.

Comparison of the two methods for calculation of abdominal circumference showed no difference by method type. Although the formula that correlated best with actual birth weight was the Shepard II formula, there was no statistically significant difference among each of the formulas evaluated (Table I). The Shepard II formula was used for subsequent comparisons with estimated gestational age and actual birth weight for analysis of outcome. Comparison of formulas for the prediction of infants weighing >750 gm and <750 gm showed no significant difference between the two groups (Table II). In the pregnancies with estimated fetal weights >750 gm, the Shepard formula I had the best correlation with actual birth weight. There was significant correlation of actual birth weight with ultrasonographic estimate of fetal weight for each gestational age group (Table III). Gestational age, actual birth weight, interval between ultrasonographic examination and delivery, fetal presentation, amniotic fluid volume, cephalic index, and fetal sex were analyzed for their potential effect on the accuracy of estimated fetal weight in predicting actual birth weight and were found to have no statistically significant influence.

Evaluation of survival by weight groups shows a significant increase in survival between the 700 and 800 gm and the 800 and 900 gm weight groups (Table IV). Therefore the 700 to 800 gm weight group was further divided into groups of ≤750 gm or >750 gm. Survival was better in the >750 gm weight group (Table V).

Evaluation of survival by gestational age showed the 50% survival breakpoint to occur at 25 weeks' gestation (Table VI). Survival was analyzed for both gestational age of <25 weeks or ≥25 weeks and estimated fetal weight of ≤750 gm or >750 gm; results are shown in Table VII. Survival using estimated gestational age ≥25

TOTAL	67	792 ± 223.6	808 ± 233.5	0.901	0.001

weeks alone was 70%. Survival using estimated fetal weight >750 gm alone was 80.5%. No difference was found in the occurrence of neonatal complications among the surviving infants when compared by actual birth weight, estimated fetal weight, or estimated gestational age, although this may be the result of the small number of cases in each group.

Comment

Several studies have documented the improved survival and long-term outcome of very-low-birth-weight infants.[2, 3] These studies have attempted to correlate neonatal mortality risk in relation to birth weight and gestational age groups, on the basis of actual birth weight and neonatal assessment of gestational age, neither of which is available to the obstetrician who manages the patient before delivery.[16] Paul et al.[6] demonstrated that there was a significant increase in neonatal mortality when the actual birth weight of the infant was underestimated before delivery. Their conclusion was that obstetricians must be aware of the tendency to underestimate fetal size on the basis of the clinical examination and that outcome might be improved by intervening for fetuses estimated to weigh ≥750 gm. Goldenberg et al.[17] reported the results of a survey of all physicians in Alabama performing obstetric care in 1978. These practicing obstetricians estimated that the 50% and the 90% survival rates were reached nearly 2 weeks later than was actually true at both their individual hospitals and the regional perinatal centers. This study emphasized the need for all physicians who practice obstetrics not only to be aware of the morbidity and mortality statistics in their hospital and region but also to be willing to manage these patients aggressively at these early gestational ages. Studies reviewing mortality rates in the very-low-birth-weight group show that with aggressive obstetric management the 50% neonatal survival has changed to an estimated gestational age and birth weight of 26 weeks and 750 gm.[1, 18] These studies also emphasize the need for aggressive management at lower gestational ages and suggest that under special circumstances aggressive management may be justified even for those infants judged to have an estimated gestational age <26 weeks.

In an attempt to study individual factors that influence survival and morbidity with very-low-birth-weight deliveries, Worthington et al.[19] presented data using actual birth weight that showed improved survival and prognosis of infants with birth weights of ≥750 gm or gestational ages >25 weeks. Their data showed birth weight to be significantly correlated with survival independent of gestational age.

At the time of our study there were no available data regarding the accuracy of ultrasonographic predictions of estimated fetal weight or a correlation of these predictions with neonatal outcome in our institution. We needed to determine the best available ultrasonographic formula for predicting actual birth weight

Table IV. Survival by weight groups

given the clinical circumstances in our institution. At that time formulas by Shepard et al.[7] and Warsof et al.[8] had been published. In our population the formula by Shepard et al., using two transverse diameters for calculation of the abdominal circumference (Shepard II), had the greatest correlation with actual birth weight, although there was no statistically significant difference among the four formulas. Key et al.[20] used similar formulas and found a high degree of correlation between ultrasonography-estimated fetal weight and actual birth weight. Their data also did not reach statistically significant difference, but they found the formula published by Warsof et al. to have a slightly greater correlation in their population. The difference between these formulas is important; we found the Warsof formula used by Key et al. to consistently estimate a lower fetal weight when compared with the formula published by Shepard et al. Using the formula of Shepard et al. instead of the formula by Warsof et al. may result in increased aggressive intervention. Since the initiation of this study other formulas have been published in the very-low-birth-weight group in an attempt to improve the accuracy of estimated fetal weight. Pielet et al.[21] showed that of the formulas evaluated that of Shepard et al. used in our study was one of four with better correlation, but the three formulas with slightly greater correlation included measurements not only of biparietal diameter and abdominal circumference but of femur length as well. It is important to use all available measurement parameters for the calculation of estimated fetal weight when available to attempt to achieve the greatest correlation.

As in the report by Key et al.,[20] our data did not show any significant effect on the accuracy of estimated fetal weight prediction caused by fetal malpresentation, amniotic fluid volume, or cephalic index.

In comparison of actual birth weight, estimated fetal weight, and estimated gestational age with survival, our data show that there was no difference in outcome when estimated fetal weight and actual birth weight were compared.

Our data also showed that when estimated gestational age and estimated fetal weight alone and in combination were compared, there was survival of ≥50% at a gestational age of 25 weeks (Table VI); when estimated fetal weight was evaluated, survival of ≥50% occurred at >750 gm (Table V). The effect of gestational age was independent of that of estimated fetal weight

Table VII. Survival by estimated gestational age and estimated fetal weight

Estimated gestational age/estimated fetal weight	*n*	*Survivors*	
		No.	*%*
<25 wk/≤ 750 gm	18	2	11.1

≤25 wk/≤750 gm	13	4	30.8
≥25 wk/>750 gm*	34	29	85.3

*Significantly different from other groups, $p = 0.001$.

(Table VII); however, if the estimated fetal weight was ≤750 gm, gestational age did not affect survival. When the estimated fetal weight was >750 gm, a gestational age ≥25 weeks was associated with improved survival. If the gestational age was <25 weeks, survival was not affected by the estimated fetal weight. However, if the gestational age was ≥25 weeks, an estimated fetal weight of >750 gm was associated with increased survival to a significant degree ($p = 0.001$). Patients in the groups associated with decreased potential survival must be managed individually. Careful attention to the management of labor, including position changes, hydration, analgesia, and oxygenation may improve neonatal outcome of these infants, particularly if there has been an underestimation of the potential for survival. Chervenak et al.[22] also reported that gestational age is more important than neonatal weight in predicting a good outcome. Howver, in the prediction of adverse neonatal outcome, both the estimated fetal weight and obstetric gestational age were significant predictors.

In conclusion, our data support a significant correlation between the ultrasound estimate of fetal weight and actual birth weight. There is no significant difference in survival and morbidity in comparison of actual birth weight with estimated fetal weight as calculated by the formula by Shepard et al. using transverse diameters to calculate abdominal circumference. In our institution, estimated gestational age and estimated fetal weight were associated independently with a 50% neonatal survival at ≥25 weeks and >750 gm, respectively. More important, if the infant had an antenatal estimated gestational age of ≥25 weeks and an ultrasonographically predicted estimated fetal weight >750 gm, neonatal survival reached 85%.

This information can be used to help guide the obstetrician in management decisions regarding the care of these very-low-birth-weight infants. In patients with uncertain dates, the ultrasonography-estimated fetal weight alone may be a better parameter to guide antepartum management. Pregnancies that are <25 weeks or <750 gm estimated fetal weight must be managed on the basis of survival data that are <50%, although careful labor management may improve outcome in this group.

Continued study is needed in this area to better clarify the potential limits of viability on the basis of both estimated gestational age and predicted fetal weight. Formulas that provide the greatest degree of correlation for the various birth weights still need to be evaluated and modified for a closer fit whenever possible. We are currently evaluating a population of patients who have been managed aggressively according to the results of this study and supported by recently published studies that also show improved outcome of infants in the same age and weight ranges.

We thank Tari Radin, RN, MSN, PhD, for assistance with the statistical analysis.

Management of selected cystic adnexal masses in postmenopausal women by operative laparoscopy: A pilot study

William H. Parker, MD, and Jonathan S. Berek, MD
Los Angeles, California

Twenty-five postmenopausal patients were predicted to have benign masses by screening criteria that included ultrasonographic findings of a cystic adnexal mass <10 cm with distinct borders and no evidence of irregular solid parts, thick septa, ascites, or matted bowel, and a normal serum CA 125 value (<35 U/ml). All 25 masses were accurately predicted to be benign. The size of the cysts on ultrasonography ranged from 3 to 9 cm with a mean of 5 cm. Twenty-two patients (88%) were successfully managed by operative laparoscopy and adnexectomy. Mean operative time was 70 minutes and mean postoperative hospital stay was 12 hours. Mean time of return to normal activity was 5 days. Three patients required laparotomy. We conclude that removal of these cystic adnexal masses by operative laparoscopy is an acceptable alternative in carefully selected postmenopausal women. (AM J OBSTET GYNECOL 1990;163:1574-7.)

Key words: Postmenopausal, adnexal mass, operative laparoscopy

The standard operative approach for adnexal masses found in postmenopausal women has been the performance of an exploratory laparotomy that allows early detection, resection, and proper staging if ovarian cancer is found. Total abdominal hysterectomy and contralateral salpingo-oophorectomy also have been advocated in the presence of benign adnexal neoplasms because of the concern for the subsequent development of a neoplasm in the contralateral ovary or uterus.[1] However, most adnexal masses in postmenopausal women are benign.[2-4] In addition, the risk of having a subsequent malignancy in a remaining pelvic organ is very low.[5,6]

If a screening process could accurately select masses that were likely to be benign, evaluation and removal with operative laparoscopic techniques would allow outpatient management with less cost and an easier recovery. The safety and efficacy of this approach have been well documented in premenopausal women with adnexal pathology.[7,8] With the use of specific ultrasonographic criteria, several authors[9-11] have been able to

accurately predict benign masses in 95% to 100% of postmenopausal patients.

Other authors[12-15] have used the CA 125 assay, which uses a monoclonal antibody that reacts to an antigen found in most nonmucinous ovarian cancers, to predict benign versus malignant pelvic masses. Finkler[16] combined ultrasonographic appearance, CA 125 values, and clinical impression to accurately predict benign masses in all postmenopausal women studied.

With a combination of preoperative ultrasonographic appearance that suggested a benign mass and normal serum CA 125 values, we selected a group of postmenopausal women who had a minimal chance of having an ovarian malignancy. The masses were then approached surgically by operative laparoscopy.

Material and methods

Candidates for this study included postmenopausal women who were found to have an adnexal mass on pelvic examination or noninvasive pelvic imaging studies and who were referred for evaluation and treatment. Postmenopausal status was defined as age over 45 years with at least 12 months of amenorrhea or a follicle-stimulating hormone >40 mIU/ml.

Twenty-five patients were consented for surgery. Patient ages ranged from 47 to 81 years with a mean of 63 years. Time from the last menstrual period ranged from 12 months to 33 years with a mean of 14 years. Eight patients (32%) had undergone prior hysterectomies for benign disease. Ultrasonographic criteria used were those modified from Herrmann.[9] Criteria for the presumptive diagnosis of a benign mass were: (1) size <10 cm; (2) cystic; (3) distinct borders; (4) no irregular solid parts or thick septa; (5) no evidence of ascites, and (6) no matted bowel. The presence of thin septa did not preclude inclusion in this study. Ultrasonographic examination was performed transabdominally with a full bladder and within 4 weeks of operation. Before surgery, one of the authors (W. P.) reviewed all scans with a radiologist for the above criteria. The size of the cysts on ultrasonography ranged from 3 to 9 cm with a mean of 5 cm.

Serum CA 125 values were considered normal if <35 U/ml. All assays were done <2 weeks before surgery and they were done in one laboratory with a radioimmunoassay kit (Centocor, Malvern, Pa.). The CA 125 values ranged from 3 to 33 U/ml with a mean of 18 U/ml.

The patient was required to be an appropriate surgical candidate. Patients were consented for adnexectomy by operative laparoscopy and for possible laparotomy. After general anesthesia was induced they had laparoscopic assessment of the pelvis and abdomen. If there was no evidence of tumor on the ovary or peritoneal surfaces and no evidence of ascites, operative laparoscopy was performed. A 10 mm laparoscope was placed through an infraumbilical incision and two or three accessory instruments were placed through suprapubic incisions. If necessary, lysis of adhesions was performed to free the adnexa. The cystic mass was then aspirated carefully to minimize the potential for fluid spill. As described by Semm[17] three no. 1 catgut endoloops were secured on the infundibulopelvic ligament and the adnexa was resected. The specimen was divided with 5 mm scissors and removed through an 11 mm accessory cannula. Frozen section was done on the removed adnexa. The procedure was terminated when the tissue was benign. If a malignancy were found, we would proceed with immediate staging laparotomy. Laparotomy was also to be performed if necessary to manage a complication or if removal of the mass by operative laparoscopy was not feasible technically.

Results

The operative findings were benign in all cases confirming the preoperative assessment. The histologic assessment of the 25 lesions were as follows: eight serous cysts, six serous cystadenomas, four serous cystadenofibromas, three paratubal serous cysts, three hydrosalpinges, and one benign retroperitoneal serous cyst.

The operative time for those patients managed by operative laparoscopy ranged from 20 to 180 minutes with a mean of 73 minutes. The duration of the postoperative hospital stay for these patients ranged from 3 to 24 hours with a mean of 12 hours. Return to normal activity ranged from 1 to 10 days with a mean of 5 days. One patient underwent operative laparoscopy during the course of a prolonged hospitalization (29 days) for a gastrointestinal and neurologic evaluation, and she is excluded from this analysis.

Two patients had complications of surgery. One patient had a perforation of the bladder with a 5 mm trocar that was managed successfully with at-home catheter drainage for 5 days. Another patient had an injury to the sigmoid colon during lysis of dense adhesions that led to laparotomy for management. Another patient had a frozen section that was inconclusive, thus requiring a laparotomy to complete the removal of a mass that was densely adherent to the pelvic peritoneum. Permanent sections revealed a benign serous cystadenofibroma.

A third patient required laparotomy when laparoscopic assessment revealed a benign paratubal cyst. Incidentally, small papillary excrescences were noted on the contralateral ovary and omentum. Biopsy specimens of these revealed metastatic carcinoma consistent with primary breast cancer that had been diagnosed 5 years earlier. Therefore exploratory laparotomy, bilateral salpingo-oophorectomy, and omentectomy were performed.

Comment

Adnexal masses may be discovered in postmenopausal women during routine examination or the evaluation of gastrointestinal or pelvic complaints. The increased use of pelvic ultrasonography and computed tomography appears to be detecting both symptomatic and incidental masses more frequently.[5] In addition, transvaginal ultrasonography is under study as a screening method for ovarian cancer and has been shown to detect asymptomatic masses that then require investigation.[18]

In 1971 Barber and Graber[19] described the "postmenopausal palpable ovary syndrome" on the basis of three patients found to have ovarian cancer in ovaries that were of normal premenopausal size. They recommended total abdominal hysterectomy, bilateral salpingo-oophorectomy because of the presumed high risk of ovarian cancer in this age group. However, subsequent studies have shown that most of these masses are benign. Flynt and Gallup[20] found that 10 of 11 patients with postmenopausal palpable ovaries had benign processes and one patient had an adenocarcinoma of the bowel. With ultrasonographic criteria similar to those applied in our study, Herrmann[9] was able to accurately predict benign masses in 177 of 185 patients (96%). In addition, all 48 purely cystic tumors <10 cm were benign and 8 of 10 stage I ovarian cancers were accurately predicted. Likewise, Goldstein[11] found that in postmenopausal women, all 28 unilocular cysts <5 cm were benign. Rulin[10] found that in postmenopausal patients, 31 of 32 adnexal masses (97%) <5 cm on ultrasonography were benign, regardless of consistency; whereas masses 5 to 10 cm were benign in 49 of 55 patients (89%). Hall and McCarthy[21] found one borderline neoplasm and 12 benign processes in 13 postmenopausal women with simple adnexal cysts <10 cm. Granberg[4] compared the gross pathologic appearance of ovarian tumors with their histologic diagnosis, and in 116 women over 50 years of age with unilocular cysts, only one (0.08%) was malignant.

CA 125, a tumor-associated surface antigen, has been studied to determine its value in preoperative differentiation of benign and malignant pelvic masses. Vasilev[12] found that 128 of 132 patients (97%) with pelvic masses who had serum CA 125 values <35 U/ml had benign masses. Of the other four patients, two had borderline lesions and only two had cystadenocarcinomas, both of the mucinous type. Einhorn[13] found that 14 of 18 patients with CA 125 values <35 U/ml had benign masses, two had borderline lesions, and two had mucinous cystadenocarcinomas. O'Connell et al.[14] found in a population referred to a tertiary center because of a clinical suspicion of ovarian cancer, all 30 patients who had a CA 125 values <35 U/ml had benign masses. Finkler[16] combined the use of ultrasonography, CA 125 values and clinical impression to evaluate adnexal masses preoperatively and found that all 10 postmenopausal patients predicted to have benign processes were accurately predicted. Similarly, Jacobs[22] found that in nine postmenopausal women with increased ovarian volumes on ultrasonographic examination and CA 125 values <30 U/ml, seven patients had benign cysts and two had a normal pelvis.

Our study also suggests that use of a combined approach with CA 125 values <35 U/ml and an ultrasonogram showing a "benign appearing" mass is a reasonable selection process. In all 25 patients the masses were accurately predicted to be benign.

Some authors have recommended removal of all pelvic organs at the time of exploratory laparotomy in postmenopausal women to remove potentially neoplastic tissue.[2] However, the risk of cancer developing in a remaining ovary that appears normal at laparoscopy in postmenopausal women should be less than the 3 to 5 per 10,000 incidence of ovarian cancer in this age-group.[5] The incidence of uterine cancer is also low in asymptomatic screened postmenopausal women (i.e., approximately 1.7 per 1000).[6] Thus the performance of a laparotomy may be discretionary in selected patients. A contralateral adnexectomy could be performed selectively, although we chose not to remove normal appearing adnexa in these patients because of the added operating time and potential morbidity.

Thought might also be given to adnexectomy by minilaparotomy in this group of patients. However, we believe that evaluation of the entire pelvis and abdomen by the laparoscope is superior to that possible during minilaparotomy. In addition, time for return to full activity should be shorter with operative laparoscopy.

Laparoscopic drainage or removal of these masses in this population has generally been avoided because of the theoretic risk of "spilling" cancer cells into the peritoneal cavity and the fear of decreasing the patients survival,[23] although this has not been documented. Dembo and colleagues[24] have presented recent evidence in a large study of 519 patients with stage I epithelial ovarian cancer that the only factors that influenced the ultimate rate of relapse and survival were the tumor grade, the presence of dense adhesions, and the presence of large volume ascites. When these factors were accounted for in a logistic regression, multivariate analysis the rate of relapse and prognosis was not influenced by rupture of the tumor. Thus the theoretic potential for tumor dissemination by rupture of a malignant cyst remains conjectural.

Some authors[25, 26] have advocated simple drainage of ovarian lesions with the laparoscope or transvaginally with ultrasonographic guidance. Kjellgren[27] found that 10% of aspiration cytologies were read as benign when, in fact, carcinoma was present. Tropé[28] was able to iden-

tify only four of 12 malignant cysts by aspiration cytology, indicating the inadequacy of this procedure for definitive diagnosis. In addition, many of the lesions in our study had functional epithelium and therefore might be expected to persist unless removed.

Goldstein[11] suggested that purely cystic masses <5 cm might be followed up with serial ultrasonographic examinations in seriously ill patients. However, without removal the diagnoses remains in question. By removing the entire adnexa with operative laparoscopy, a complete specimen is provided for precise pathologic analysis and persistence is precluded. Orlando[29] showed that in 345 patients over the age of 60 years who had laparoscopy the complication rate was no different than in 1500 younger patients. Our study also showed that operative laparoscopy is well tolerated in postmenopausal women and that the hospital stay and the time to recovery are shorter than expected from laparotomy. We believe that removal of these adnexal masses is appropriate, and that management by operative laparoscopy allows an acceptable alternative in carefully selected postmenopausal women. More accurate tumor markers and the use of vaginal ultrasonography might enhance the selection process.[30]

Hyperadrenergic orthostatic intolerance as a result of postpartum blood loss

Scott L. Mader, MD, Judith A. Mackall, MD, and Martin P. Emert, MD
Cleveland, Ohio

This article describes a young women in whom orthostatic intolerance developed as a result of protracted postpartum vaginal bleeding. The cardiovascular abnormalities were unresponsive to usual treatment measures, and she required combination therapy directed at increasing plasma volume and decreasing sympathetic nervous system activity. After resolution of her symptoms, the patient required no long-term therapy. Chronic blood loss has not been reported as a cause of this syndrome. (Am J Obstet Gyneco. 1990;163:1578-9.)

Key words: Hypotension, postpartum, hyperadrenergic

Orthostatic hypotension usually results from two major causes. It can occur as a result of an inadequate nervous system response that is a result of central or peripheral nervous system dysfunction from disease or medications. Orthostatic hypotension can also occur as a result of excessive stress to the cardiovascular system, such as a decrease in blood volume, or vasodilation. Patients in this latter group often demonstrate a supranormal heart rate response and narrowing of the pulse pressure; the condition is also known as hyperadrenergic orthostatic intolerance. We report a case of hyperadrenergic orthostatic intolerance that developed after chronic postpartum blood loss that was not reversible with volume replacement. Chronic blood loss has not been previously reported as a cause of this disorder.

Case report

The patient was a 30-year-old black woman with no previous medical problems. Six weeks before admission she had an uncomplicated vaginal delivery of her fifth child. Four weeks before admission heavy vaginal bleeding developed and the patient was seen in the emergency room for syncope. She was markedly orthostatic and had a hematocrit value of 17%. The patient had transfusion on two occasions and was admitted 2 weeks later because of continued bleeding. She had curettage that showed retained placental products. She was discharged with iron sulfate therapy, 325 mg three times a day, as her only medication. The patient was seen in the emergency room two additional times within the following week. Both times she was markedly orthostatic and tachycardic with a stable hematocrit level. She was treated with normal saline solution fluid replacement and her symptoms and blood pressure improved. However, her symptoms recurred after several hours.

On the day of admission the patient again complained of dizziness, palpitations, and weakness. She denied flushing, nausea, vomiting, diarrhea, polydypsia, polyuria, or vaginal bleeding. She denied any medication use other than iron sulfate. On examination, her sitting blood pressure was 140/100 mm Hg with a pulse of 92 beats/min; standing blood pressure was 120/80 mm Hg with a pulse of 176 beats/min. The remainder of the examination was unremarkable including skin turgor, cardiac, neurologic, rectal, and pelvic findings. She received 4 L of normal saline solution in the emergency room before admission.

Physical examination on admission to the medical floor showed a thin, black woman who was nervous but otherwise comfortable. Her temperature was 36.8° C, supine blood pressure 138/82 mm Hg with pulse of 76 beats/min, sitting blood pressure 122/84 mm Hg with pulse of 96 beats/min, and a standing pulse of 120 beats/min. The lungs were clear to auscultation. Cardiovascular examination showed a normal point of maximal impulse, jugular venous pressure of 6 cm, and normal S_1 and S_2 sounds with no appreciable murmur. The abdomen was normal, and digital rectal examination showed guaiac-negative stool. A pelvic examination was unremarkable with no vaginal discharge or bleeding.

Laboratory test samples drawn before saline solution infusion in the emergency room included hematocrit of 33%, white blood cell count of 6×10^9/L, a platelet count of 271×10^9/L, and a reticulocyte count of 3.9%. The erythrocyte sedimentation rate was 7 mm/hr. Serum electrolyte analysis showed the following levels: sodium, 138 mmol/L; potassium, 4.6 mmol/L; chloride, 103 mmol/L; bicarbonate, 23

6/1/23227

mmol/L; and glucose, 4.33 mmol/L. A urine toxicology screen was negative. An electrocardiogram showed borderline sinus tachycardia; the chest x-ray film was normal.

The patient's hospital course was remarkable for continued orthostasis despite aggressive rehydration. The following tests were obtained and had normal results: pelvic ultrasonography, thyroid function tests, urine electrolytes and specific gravity, cosyntropin stimulation test, aldosterone, prolactin, luteinizing hormone, follicle-stimulating hormone, echocardiogram, and computerized tomography of the head. Autonomic function testing was performed on the fifth hospital day and is shown in Table I.

The patient was treated with fludrocortisone, 0.1 mg twice daily; atenolol, 50 mg daily, high-salt diet, elevation of the head of the bed with blocks, and was instructed to spend as much time as possible in the upright position. On this regimen her condition improved after 2 days and her weight increased approximately 3 kg over the next week. Follow-up blood pressure readings are shown in Table I. All medications were tapered after 1 month with no recurrence of symptoms and no change in orthostatic blood pressure parameters.

Table I. Autonomic function testing results

Condition	*Blood pressure (mm Hg)*	*Pulse (beats/min)*
Pretreatment		
Supine	122/79	102
Standing	121/93	136
Walking	112/88	136
Isometric handgrip	+11/+19	+20
Cold pressor	+10/+5	+10
Supine after standing	+30/+10	−46
After treatment		
Supine	124/80	80
Standing	114/78	88
Walking	117/77	93

All readings were taken with an automated blood pressure cuff (Physiocontrol Lifestat, Redmond, Wash.). Supine readings are the mean of the second and third readings after 5 minutes of supine rest. Standing values are after 60 seconds in the upright position. Walking values are values after 5 minutes of standing and 2 minutes of walking. Isometric handgrip is the maximum change from baseline during 3 minutes of 30% maximal handgrip. Cold pressor is the maximum change from baseline after 1 minute of hand immersion in ice water.

Comment

This patient appeared to have orthostatic intolerance as a result of prolonged blood loss after a spontaneous vaginal delivery. However, despite the appropriate corrective measures (saline solution infusion, blood transfusion), she continued to have orthostatic symptoms with prominent tachycardia. She responded to combination treatment with a high-salt diet, elevation of the head of the bed, fludrocortisone, and β-blockade. When her blood pressure normalized, all treatment measures were stopped and she remained asymptomatic.

This type of orthostatic hypotension (with prominent tachycardia and narrowing of the pulse pressure) has also been called hyperadrenergic orthostatic intolerance, sympathotonic orthostatic hypotension, irritable heart syndrome, vasoregulatory asthenia, hyperkinetic heart syndrome, or hyperdynamic β-adrenergic circulatory state.[1] The hallmark of this condition is normal autonomic function with a brisk tachycardia to upright posture and relative maintenance of diastolic pressure.

Hyperadrenergic orthostatic intolerance can be seen with many conditions, including cardiac disease (mitral valve prolapse, paroxysmal tachycardias, atrial myxoma, hypertrophic cardiomyopathy), deconditioning (prolonged recumbency or space travel), inadequate blood volume (dehydration, bleeding, renal salt wasting, adrenal insufficiency, pheochromocytoma, diuretic use), excessive pooling (large varicose veins, pregnancy, or sympathectomy), excessive vasodilation (fever, medications, hypokalemia, hyperbradykininism, hot bathing, strenuous exercise), and other miscellaneous causes (idiopathic, postviral, or during rapid weight loss).

The pathophysiologic characteristics of hyperadrenergic orthostatic intolerance are not understood. Several investigators[2, 3] have studied this syndrome; from the data there appear to be components of autonomic nervous system hyperresponsiveness, volume depletion, and excessive venous pooling. The initiating event in most patients is not known. In our patient it appears that the primary event was blood loss caused by retained placental products. An important factor may have been the extended blood loss over a 2-week period before definitive treatment to stop the bleeding. As a result of the decreased blood volume, compensatory sympathetic nervous system overactivity developed. At this point, further attempts to reverse volume state were unsuccessful because of vasoconstriction caused by the sympathetic nervous system overactivity. Except for standing tachycardia and orthostasis, observation of her clinical state would suggest that her volume status was normal because she was not thirsty, had normal skin turgor, and had normal jugular venous pressure. Only after combination treatment with volume expansion, elevation of the head of the bed, and β-blockade (to decrease sympathetic nervous system outflow) did her symptoms resolve. Use of clonidine may have been equally efficacious to β-adrenergic blockade.[2]

Cervicovaginal microflora and pregnancy outcome: Results of a double-blind, placebo-controlled trial of erythromycin treatment

James A. McGregor, MDCM,[a] Janice I. French, CNM, MS,[a] Ruth Richter, CNM, MSN,[a] Margo Vuchetich, BSN,[a] Vaundeen Bachus, BSN,[a] Kyung Seo, MD,[a] Sharon Hillier, PhD,[b] Franklyn N. Judson, MD,[c] John McFee, MD,[c] Judith Schoonmaker, PhD,[a] and James K. Todd, MD[d]

Denver, Colorado, and Seattle, Washington

Available information suggests that some instances of preterm birth or premature rupture of membranes are associated with clinically unrecognized infection and inflammation of the lower uterine segment, decidua, and fetal membranes. Various cervicovaginal microorganisms have been recovered from these sites. Many of these microorganisms produce factors that may lead to weakening of the fetal membranes, release of prostaglandins, or both. This study evaluated the presence of various lower genital tract microflora and bacterial conditions in 229 women enrolled in a double-blind, placebo-controlled trial of short-course erythromycin treatment at 26 to 30 weeks' gestation to prevent preterm birth. Demographic, obstetric, and microbiologic parameters were prospectively evaluated. Premature rupture of membranes occurred less frequently ($p < 0.01$) among women who received erythromycin (6%) versus placebo (15%). Preterm premature rupture of membranes also occurred less frequently, although not significantly ($p = 0.3$) in patients who received erythromycin (2%) versus placebo (5%). Erythromycin treatment significantly decreased the occurrence of premature rupture of membranes among women who were initially positive for *Chlamydia trachomatis* infection. Logistic regression analysis demonstrated that *C. trachomatis* ($p = 0.05$; odds ratio, 9), vaginal wash phospholipase C ($p = 0.08$; odds ratio, 6) and prior preterm birth ($p = 0.007$; odds ratio 17) were associated with increased risk of preterm birth. Bacterial vaginosis, *Mycoplasma hominis, Ureaplasma urealyticum* were not significantly associated with increased risk of preterm birth or preterm rupture of membranes. These findings support a role for selected lower genital tract microflora in preterm birth and premature rupture. Large controlled treatment trials of specific infections or conditions associated with preterm birth and premature rupture of membranes are required to confirm the value of antimicrobial treatments in prevention of microbial-associated preterm birth. (Am J Obstet Gynecol 1990;163:1580-91.)

Key words: Prematurity, premature rupture of membranes, infection, antibiotic, treatment, prevention

Gestational age and birth weight are the most important biologic determinants of an individual's chances for survival and healthy growth and development.[1] Approximately 300,000 infants are born in the United States each year with the biologic disadvantages of prematurity. Of these approximately 15% to 20% die in the newborn period.[1]

To be maximally effective in prevention of preterm birth, intervention strategies should be cause specific and based on understanding of pathophysiology. Much information indicates that infectious processes and resultant inflammation in and around the uteroplacental unit are involved in the pathogenesis of a proportion of women who suffer preterm labor, premature rupture of membranes, and premature birth.[2] Mechanisms by which cervicovaginal microflora and host inflammatory cells may act to mediate preterm birth require further elucidation. Cervicovaginal microorganisms may gain access to the lower uterine segment through the cervix and directly mediate infection involving the decidua, the chorioamnion, and possibly the placenta. Such infections may be initially unrecognized, and if uncontained, can progress to clinically apparent chorioamnionitis with intraamniotic fluid in-

fection and possible fetal sepsis.[3] Cervicovaginal microflora and host inflammatory cells may also mediate or promote preterm labor or preterm rupture of membranes through the release of various phospholipases and proteases.[4, 5]

Attempts to improve pregnancy outcome with antimicrobial treatment to eliminate specific lower urogenital tract microorganisms remain inconclusive but encouraging. Elder et al.[6] noted increased birth weight among newborns of women without bacteriuria who were treated antenatally with a 6-week course of tetracycline.[6] In an attempt to eliminate genital infections caused by *Ureaplasma urealyticum, Mycoplasma Hominis,* or both organisms among pregnant women, Kass et al.[7] and McCormack et al.[8] demonstrated increased birth weight among newborns of pregnant women who received erythromycin for up to 6 weeks during the third trimester. Neither study specifically discussed the occurrence of preterm premature rupture of membranes or the presence of other various genitourinary tract microflora. Recently Nugent et al. were unable to demonstrate benefits from antenatal erythromycin treatment in women colonized with *U. urealyticum* but not *M. hominis,* group B streptococcus, or *Chlamydia trachomatis* (Nugent RP, et al., Society for Epidemiologic Research Abstracts, 1989;929-30). In a study focused on women with group B streptococcal urinary tract colonization, Thomsen et al.[9] reported a reduction in the occurrence of premature rupture of membranes and preterm birth among women treated with penicillin. Among women hospitalized with preterm labor who received parenteral tocolytic therapy, several studies have shown mixed results of erythromycin or ampicillin treatment or a combination of the two drugs in prolonging pregnancy.[10, 11]

We undertook this study to prospectively evaluate associations of cervicovaginal microflora and selected lower genital tract microbe-associated factors with pregnancy outcomes. We used a short course of orally administered erythromycin to "probe" the relationship of these microbial factors or conditions with obstetric and neonatal outcomes including premature rupture of membranes, preterm premature rupture of membranes (<37 weeks' gestation), gestational length, birth weight, and newborn infection in a group of inner-city pregnant women.

Methods

From October 1985 to August 1988, 235 women between 26 and 30 weeks' gestation who attended publicly supported antenatal clinics in the Denver metropolitan area were enrolled in this prospective double-blind, placebo-controlled study. Prior evaluations of unselected women at these same inner-city sites showed rates of preterm birth between 16% to 20%, with the majority of these births occurring after 26 weeks' gestation (John McFee, MD, personal communication). In the studies by Kass et al.[7] and McCormack et al.,[8] only erythromycin given in the third (vs second) trimester of pregnancy was associated with increased birth weight. Therefore we enrolled and treated patients between 26 and 30 weeks' gestation.

Written informed consent was obtained as approved by the institutional human subjects committees. Women were excluded if they had a recognized cause for prematurity (multiple gestation, placenta previa, or cervical incompetence); if they had severe cardiac, renal, respiratory or immunologic diseases; or if they were allergic to erythromycin. Subsequently six women were excluded from analysis: four women were lost to follow-up after enrollment, one was treated for premature labor on the day of enrollment, and one woman experienced intrauterine fetal death at 30 weeks' gestation. The total evaluated sample included 229 women and their newborns.

Clinical evaluation. Women were enrolled by one of three experienced clinicians. Participants were interviewed to obtain demographic, social, behavioral, sexual, medical, and obstetric information. Specific information regarding urogenital symptoms was recorded.

A vaginal speculum examination was performed and characteristics of vaginal discharge (consistency, amount, color, odor) were recorded on standard forms. Samples were obtained as follows. One milliliter of saline solution was inoculated with a cotton swab containing vaginal fluid for microscopic examination for *Trichomonas vaginalis,* yeast pseudohyphae, and release of amine odor with addition of 10% potassium hydroxide "whiff test." This sample was then held at 4° C and evaluated in the laboratory for nonspecific protease activity using Azocoll substrate.[5] Vaginal fluid pH was assessed directly with Nitrazine paper (Squibb, Princeton, N.J.) and recorded as >4.5 or ≤4.5. An additional sample of vaginal fluid was allowed to air dry on a slide for Gram stain evaluation of bacterial vaginosis and *Mobiluncus* spp. morphotypes.[12]

Separate endocervical swabs were immediately inoculated onto a chocolate agar and a modified Thayer-Martin split plate for the recovery of *Neisseria gonorrhoeae* organisms, and into sucrose-phosphate glutamate transport media for recovery of *C. trachomatis.* Cervicovaginal swabs were inoculated onto 5% sheep blood agar (tryptic soy base, Remel, Denver) for recovery of group A streptococcus, group B streptococcus, *Staphylococcus aureus, Gardnerella vaginalis,* and yeast organisms. These microorganisms were identified with standard techniques. Additional vaginal swabs were inoculated into a standard mycoplasma medium for recovery of *M. hominis* and *U. urealyticum.* Cultures for *C. trachomatis, M. hominis,* and

U. urealyticum specimens were frozen at −70° C and processed in batches. After 48 hours' incubation at 35° C, inoculated cycloheximide-treated McCoy cell monolayers were treated with fluorescence-conjugated anti-chlamydia monoclonal antibody (Syva Microtrak, Syva Co., Palo Alto) and examined microscopically for the presence of stained inclusions. Negative cultures were blind passaged once and reprocessed. *M. hominis* and *U. urealyticum* organisms were cultured and identified with the Mycotrim GU Triphasic Culture System (Hana Biologics, Inc., Alameda, Calif.)

After microbial samples were obtained and vaginal pH was determined, the posterior vaginal fornix was irrigated with 4 ml of sterile Dulbecco's buffered saline solution and after standardized mixing was aspirated into a sterile syringe. The vaginal wash specimens were frozen immediately at −20° C, then frozen at −70° C within 4 hours of collection. Wash samples were evaluated in batches for nonspecific protease,[5] phospholipase C,[13] and total protein (Biorad, Richmond, Calif.).

Proline aminopeptidase was quantified in these samples by a modification of the method of Thomasen et al.[14] Vaginal samples were incubated for 4 hours with proline nitroanilide (0.2 gm/100 ml Tris buffer) at 37° C, 6% carbon dioxide. Samples were read at 450 nm and compared with standard leucine aminopeptidase for quantitation.

Treatment and follow-up. After initial examination the women were given a sealed bottle containing 21 tablets and were instructed to take one tablet three times a day for 1 week, and to record when they took the tablet on a medication diary. Treatment was prepared and randomized by means of a computer-generated random number list by The Upjohn Company (Kalamazoo). Women received identical-appearing treatment bottles and tablets that were either erythromycin base (E-Mycin, Upjohn) 333 mg, or placebo. Patients continued routine prenatal care after enrollment in the study.

Two to four weeks after enrollment the women were seen by one of the investigators during a routine prenatal visit; diaries and bottles were collected and unused pills were counted. Women were questioned regarding side effects, sexual activity, and signs and symptoms of vaginitis before repeat vaginal sampling.

Only positive *N. gonorrhoeae* cultures were reported to health care providers. Except for one patient with *N. gonorrhoeae* infection, sexual partners of patients were not referred for evaluation and treatment. Maternal and newborn medical records were reviewed to obtain additional information on antenatal, intrapartum, and postpartum maternal course and the newborn course through 3 months of age. If records were unavailable the data were obtained by telephone calls and written correspondence to private physicians and patients.

Definitions. Gestational age was determined before data analysis and based on best clinical criteria, which included last menstrual period, fetal growth, and ultrasonographic measurements, and newborn gestational age assessment.[15] Preterm labor was defined as regular uterine contractions (two or more in 10 minutes) treated with hospitalization and at least one subcutaneous injection or intravenous infusion of tocolytic agent followed by oral tocolytic therapy, or labor that resulted in a preterm birth. Patients with preterm labor that followed preterm premature rupture of membranes were not counted as preterm labor patients. Premature rupture of membranes was defined as rupture of membranes at least 1 hour before the onset of uterine contractions. Preterm premature rupture of membranes was defined as rupture of membranes before labor (as above) before 37 weeks' gestation. Preterm birth was considered as birth before completion of 37 weeks' gestation. Infants who weighed <2500 gm at birth were considered low birth weight.

Data analysis. Data were summarized by use of descriptive statistics. Statistical significance of treatment group differences and other univariate associations were tested with χ^2 or Fisher's exact test (two-tailed). Continuous data were analyzed with Student's t test. When appropriate, the relative risk and 95% confidence intervals were calculated. Findings from initial microbiologic tests were analyzed for associations with pregnancy outcomes. To control the effects of multiple independent variables on the development of preterm birth, low birth weight, and premature rupture of membranes, logistic regression analyses were performed with the SAS LOGIST program (SAS Institute Inc., Cary, N.C.) on a VAX computer. Multivariate analysis was not attempted for the dependent variables preterm premature rupture of membranes or preterm birth without prior premature rupture of membranes because of the small number of women with these outcomes. Alpha was set at 0.05 for both univariate and multivariate analysis. The Breslow-Day test for homogeneity of results of odd ratios was used to confirm significance as appropriate.

Results

The demographic aspects of study women are described in Table I. There were no differences between demographic, historical, or behavioral characteristics for the 119 women randomized to receive erythromycin and the 110 women who received placebo. Use of "crack" or cocaine was reported by five women who received erythromycin and two who received placebo. Each of these women was delivered at term.

Reported signs and symptoms of vaginitis and characteristics of vaginal discharge were similar between study groups. Approximately 5% of patients in each group noted vaginal irritation, itching, or burning at

enrollment. No patient was diagnosed with vaginitis by her regular health care provider on the day of study enrollment.

Recovery rates for the test microorganisms and vaginal substances were similar at study enrollment among the patients randomized to receive erythromycin or placebo, except that women randomized to the placebo group more often had vaginal pH >4.5 (Table II).

Follow-up examination was performed approximately 1 month ($\bar{x}$ = 27 days) after study enrollment for 75 (63%) women who were treated with erythromycin and 81 women (74%) who were given placebo. Vaginal recovery of *M. hominis* among women who received erythromycin was 24% at intake and 12% after treatment (Table II). However, among the nine women treated with erythromycin who were positive for *M. hominis* at entry and available for reexamination, seven remained positive at follow-up. Detection of *C. trachomatis* and *Mobiluncus* spp. morphotypes among women who were initially positive was decreased after erythromycin treatment, but not significantly (p = 0.1, data not shown). Detection of group B streptococcus, bacterial vaginosis, *U. urealyticum, Staphylococcus aureus, G. vaginalis,* yeast species, proline aminopeptidase, levels of vaginal phospholipase C, nonspecific protease, and vaginal pH >4.5 did not differ from pretreatment levels or prevalence after erythromycin treatment (Table II).

Antenatal complications. Various medical problems were experienced by 19 (16%) patients in the erythromycin group and 11 (10%) patients in the placebo group (p = 0.2). These complications were well controlled and not implicated in preterm birth, except for one patient in the placebo group who was diagnosed with systemic lupus erythematosus (preterm delivery with premature rupture of membranes) and one patient treated with erythromycin who required antihypertensive and asthma-related medications (delivery at term).

Twenty-five percent of patients in the erythromycin group and 16% of patients in the placebo group reported antenatal vaginal bleeding (p = 0.1). One patient in the placebo group was diagnosed with a low-lying placenta that resolved; she was delivered at term without further complications. An additional patient in the erythromycin group was diagnosed with placenta previa after study enrollment. This patient was seen with complaints of preterm premature rupture of membranes at 33 weeks' gestation; she was delivered at 36 weeks by cesarean section after demonstration of fetal lung maturity.

Seven women in the erythromycin group (6%) and five women in the placebo group (4%) were followed up for gestational diabetes. Polyhydramnios developed in two women in each treatment group, and three women in the erythromycin group (2%) and one (1%) patient who received placebo had oligohydramnios. Seven (6%) patients in the erythromycin group and five (4%) patients in the placebo group were followed

up for intrauterine growth retardation. Pregnancy-induced hypertension was diagnosed among four (3%) erythromycin patients and four (4%) placebo patients antenatally. Each was delivered at term.

Two patients experienced intrauterine fetal death, one of undetermined cause at 30 weeks in a patient in the placebo group and one fetus with Down's syndrome at 42 weeks in a women in the erythromycin treatment group. The patient with the 30-week-gestation fetal death was not considered in analysis for preterm outcome variables; all other patients with concurrent or intercurrent antenatal medical or obstetric problems were included in the analysis.

Sixty-six percent of the erythromycin group and 69% of the placebo group received nonprotocol antimicrobial therapy during antenatal care. No patient received antibiotics within 2 weeks of study treatment. The preponderance of treatments occurred before study entry (first trimester: 21%; second trimester: 40%; third trimester: 37%). Vaginitis was the most common reason for antimicrobial treatment. Approximately 20% of both groups received treatment during pregnancy for a single urinary tract infection.

Compliance. The mean number of study pills taken differed between groups (erythromycin, 15.9 ± 7.8; placebo, 17.8 ± 5.9; $p = 0.05$). Only 73% of women randomized to receive erythromycin and 84% of women who received placebo completed 4 or more days of study treatment ($p = 0.04$). Side effects, including nausea, vomiting, and diarrhea, were reported significantly ($p < 0.05$) more often among women who received erythromycin (nausea: erythromycin = 27%; placebo = 13%; $p = 0.01$; vomiting: erythromycin = 13%; placebo = 4%; $p = 0.02$; diarrhea: erythromycin = 5%; placebo = 0; $p = 0.03$).

Pregnancy outcome. Spontaneous vaginal delivery occurred among 80% of patients in the erythromycin group and 71% of placebo patients. Cesarean section delivery was performed for 8% and 12% of patients who received erythromycin and placebo, respectively. Assisted vaginal delivery occurred in the remaining patients.

There were no overall differences in the occurrence of preterm labor, preterm birth, or low-birth-weight infants among treatment groups when the data were analyzed by univariate analysis. The mean gestational age at delivery was 39.3 ± 1.9 weeks among patients in the erythromycin group and 39.2 ± 1.6 weeks for those who received placebo. Mean birth weight was 3132 ± 588 gm among erythromycin patients and 3099 ± 548 gm among placebo patients ($p = 0.7$). Further analysis showed no difference in gestational age or birth weight at delivery even for those patients who had completed at least 4 days of study treatment [gestational age at delivery: erythromycin ($N = 87$), 39.3 ± 1.7 weeks; placebo ($N = 93$), 39.4 ± 1.6 weeks; birth weight: erythromycin, 3191 gm; placebo, 3161 gm] or those who completed the full 1 week of study treatment [gestational age at delivery: erythromycin ($N = 57$), 39.2 ± 1.7 weeks; placebo ($N = 60$), 39.4 ± 1.6

weeks; birth weight: erythromycin, 3195 gm, placebo, 3180 gm].

Two patients in the erythromycin group (2%) and three (3%) patients in the placebo group were treated for clinically diagnosed chorioamnionitis. Postpartum endometritis occurred among six (6%) patients in the erythromycin group and eight (8%) in the placebo group. There were no significant differences between study groups for any neonatal outcome evaluated.

Premature rupture of membranes. Rupture of membranes before labor occurred significantly more often among women who received placebo (16%) compared with those who received erythromycin (6%), ($p = 0.01$; relative risk, 0.4; 95% confidence interval, 0.2 to 0.8). Preterm premature rupture of membranes occurred among seven women and was also decreased among women in the erythromycin group, although this failed to reach statistical significance (erythromycin, 2%; placebo, 5%; $p = 0.3$; relative risk, 0.4; 95% confidence interval, 0.1 to 1.8).

Trends were noted between selected medical factors and premature rupture of membranes; more women who experienced premature rupture of membranes gave a history of prior sexually transmitted disease (erythromycin, 15%; placebo, 7%; $p = 0.06$, relative risk, 2; 95% confidence interval, 1.0 to 4.9) and women who experience preterm premature rupture of membranes more often had a history of a single prior abortion (erythromycin, 7%; placebo, 2%; $p = 0.08$; relative risk, 4; 95% confidence interval, 0.9 to 14.8). None of the other demographic, behavioral or other medical problems analyzed were significantly associated with increased risk of premature rupture of membranes or preterm premature rupture of membranes.

Overall, premature rupture of membranes (any gestational age) occurred significantly more often among women from whom *C. trachomatis* was recovered at study enrollment ($p = 0.03$; relative risk, 2.5; confidence interval, 1.1 to 5.7) and also among those with vaginal pH >4.5 ($p = 0.03$; relative risk, 2.5; 95% confidence interval, 1.1 to 5.5). Women with *U. urealyticum* infection experienced premature rupture of membranes more frequently; however, this did not reach statistical significance ($p = 0.08$, relative risk, 5.0, 95% confidence interval, 0.9 to 27.8).

To test for effects of erythromycin treatment on pregnancy outcomes, data were stratified according to the presence of susceptible microorganisms or abnormal vaginal conditions. None of the 13 women treated with erythromycin from whom *C. trachomatis* was initially recovered experienced premature rupture of membranes. Conversely, six of 12 women with positive *C. trachomatis* cultures who received (50%) placebo experienced premature rupture of membranes ($p = 0.03$, relative risk, 0.4; 95% confidence interval, 0.2 to 0.8). The Breslow-Day test for homogeneity of results of odds ratios confirmed this significant difference ($p = 0.03$). Among women from whom *U. urealyticum* was recovered, the occurrence of premature rupture of membranes was significantly less in those who received erythromycin (erythromycin, 7%; placebo, 18%, $p = 0.03$; relative risk, 0.4; 95% confidence interval, 0.1 to 0.9); among women who were negative for *U. urealyticum*, only a single patient in the placebo group experienced premature rupture of membranes (Breslow-Day test, NS). Among the women with vaginal pH >4.5, women in the erythromycin group experienced premature rupture of membranes less often, although not significantly (erythromycin, 4%; placebo, 24%; $p = 0.07$; relative risk, 0.2; 95% confidence interval, 0.03 to 0.96).

Preterm premature rupture of membranes occurred more often among women whose initial cultures were positive for *S. aureus* (erythromycin, 2/12 [17%]; placebo, 5/209 [2%]); ($p = 0.04$; relative risk, 7; 95% confidence interval, 1.8 to 28.4). Women with positive findings at enrollment for *C. trachomatis*, *T. vaginalis*, group B streptococcus, yeast species, phospholipase C, positive whiff test, and pH >4.5 also experienced preterm premature rupture of membranes more frequently; however, these associations failed to reach statistical significance.

Preterm birth. Preterm birth occurred among eight (7%) women in the erythromycin group and nine (8%) women who received placebo. History of a prior preterm birth was the only historical, demographic, or behavioral variable significantly associated with preterm birth in the current pregnancy ($p = 0.002$; relative risk, 4; 95% confidence interval, 1.7 to 9.9). Recovery of *C. trachomatis* was significantly associated with increased risk of preterm birth ($p = 0.03$; relative risk, 3; 95% confidence interval, 1.2 to 8.1). A positive whiff test was also significantly associated with increased risk of preterm birth ($p = 0.04$; relative risk, 3; 95% confidence interval, 1.1 to 7.6) as was the presence of both pH >4.5 and a positive whiff test ($p = 0.03$; relative risk, 4; 95% confidence interval, 1.3 to 10.6). Vaginal pH >4.5 alone was not significantly associated with increased risk of preterm birth ($p = 0.2$; relative risk, 2; 95% confidence interval, 0.7 to 5.1). Overall, bacterial vaginosis (determined by Gram stain) and positive proline aminopeptidase were not associated with preterm birth. Preterm birth occurred more frequently, but not significantly, among the small number of women with *T. vaginalis*, *S. aureus*, and increased phospholipase C found at initial examination.

Preterm birth occurred before completion of 34 weeks' gestation in five patients. *C. trachomatis* ($p = 0.01$; relative risk, 11; 95% confidence interval, 2.8 to 46), *M. hominis* ($p = 0.008$; relative risk, 26; 95% con-

fidence interval, 1.4 to 494), proline aminopeptidase ($p = 0.04$; relative risk, 8; confidence interval 95%, 1.2 to 48), pH >4.5 ($p = 0.07$; relative risk, 8; 95% confidence interval, 1.1 to 50), and positive whiff test ($p = 0.02$; relative risk, 11; 95% confidence interval, 2.5 to 44) were significantly associated with increased risk of birth ≤34 weeks' gestation. Of note, four of these five women had findings of multiple microbiologic factors thought to be associated with increased risk of prematurity (Table III).

Preterm birth in the absence of premature rupture of membranes occurred among nine women and significantly more often among women with both vaginal pH >4.5 and positive whiff test ($p = 0.03$; relative risk, 6; 95% confidence interval, 1.6 to 19.5). Similarly, preterm birth without prior rupture of membranes occurred more frequently, but not significantly, among women who were positive for *C. trachomatis* ($p = 0.07$), *T. vaginalis, M. hominis,* proline aminopeptidase ($p = 0.09$), whiff test, and phospholipase C.

Multivariate analysis. Logistic regression analysis was performed to control for the effects of multiple independent variables on the occurrence of preterm birth, low birth weight, or premature rupture of membranes (Table IV). As a preliminary step, a logistic regression analysis was performed to identify significant independent variables from among maternal demographic, behavioral, and past medical history variables that were predictive of preterm birth, low birth weight, or premature rupture of membranes, Among these independent variables (maternal age, ethnic group, marital status, gravidity, prior abortion, prior preterm birth, use of alcohol, street drugs, smoking, and history of pelvic inflammatory disease), only prior preterm birth was significantly associated with preterm birth and low birth weight ($p = 0.001$).

Second, on the basis of results of previously published studies or theoretical associations, another model was constructed that included bacteriologic findings (*C. trachomatis, T. vaginalis, U. urealyticum, M. hominis, S. aureus,* bacterial vaginosis), vaginal enzymes (high vaginal nonspecific protease, phospholipase C), vaginal pH >4.5, treatment group, use of other antenatal antibiotics, and prior preterm birth. In this second model (Table IV), *C. trachomatis* ($p = 0.05$; OR, 9), phospholipase C ($p = 0.08$; OR, 6) and prior preterm birth ($p < 0.01$; OR, 17) were associated with preterm birth. After adjusting for the effects of the other independent variables in the model, erythromycin treatment was associated with decreased risk of preterm birth ($p = 0.06$; OR, 0.1).

A final model was created that included only the independent variables that were statistically significant or bordered on statistical significance (*C. trachomatis,* phospholipase C, prior preterm birth, and study treatment). In this final model, *C. trachomatis* ($p = 0.02$; OR, 4) and prior preterm birth ($p = 0.009$; OR, 5) were the only variables associated with increased risk of preterm birth.

In similar analyses, low birth weight (<2500 gm) was positively associated with prior preterm birth ($p = 0.003$, OR, 8) and negatively associated with erythromycin treatment ($p = 0.02$, OR, 0.2); and erythromycin treatment was associated with decreased risk of premature rupture of membranes ($p = 0.01$; OR, 0.1) (Table IV).

Because of the small number of women who experienced preterm premature rupture of membranes, preterm birth ≤34 weeks' gestation, and preterm birth in the absence of prior premature rupture of membranes, these outcomes were not evaluated with multivariate techniques.

In this study, cervical infection with *C. trachomatis* accounted for 20% of the preterm birth (population attributable risk). Such calculations are probably oversimplifications because an individual mother's host susceptibility and the presence of different microorganisms are not considered.

Comment

We prospectively studied 229 pregnant women and their singleton infants to identify and measure associations of various demographic, obstetric, behavioral, and reproductive tract microbiologic–related factors with subsequent maternal and neonatal outcomes. We further used a short, defined course of oral enteric-coated erythromycin base to more dynamically assess possible microbiologic relationships and pregnancy outcomes. Study patients were inner-city women typical of those treated at public teaching hospitals. There were no significant differences between the drug- or placebo-treated groups in demographic, historical, obstetric, behavioral, or microbiologic-related parameters at study entry, except for an increased number of women with high vaginal pH among placebo patients. Findings were typical of similar populations.[10, 15-17] Rates of intercurrent, antenatal, intrapartum, and neonatal complications also appeared typical of this population.

The relatively low incidence (7% to 8%) of preterm birth among enrolled women was probably a result of selection biases imposed by entry criteria. Overall rates (16% to 20%) of preterm birth for the clinics studied did not change during the course of this study. Perhaps because of increasing interest in possible associations of infection and preterm birth, approximately two thirds of the women in both groups received nonstudy antimicrobials from antenatal care providers. It might be expected that additional antibiotics would obscure detection of study treatment effects. However, when nonstudy antimicrobial therapy was analyzed by logistic regression, no association with preterm birth, low birth weight, or premature rupture of membranes was noted.

Neither the women who received erythromycin nor women treated with placebo tolerated study medication well; only 73% of the erythromycin and 84% of the group placebo completed at least 4 days of medication. Significantly, more women who took erythromycin complained of nausea and vomiting and took fewer tablets. This relatively poor compliance may have been caused by (1) general reticence to take medications during pregnancy, (2) inadequate understanding or identification with overall study goals, (3) lack of a specific treatment indication (i.e., treatment of an acknowledged pathogen), or (4) other factors. Other than

nausea, vomiting, and diarrhea, there were no other recognized complications of erythromycin treatment among women or newborns.

Univariate analysis of intake findings and subsequent preterm birth or premature rupture of membranes showed that occurrence of a prior preterm birth was the only nonmicrobiologic factor linked with preterm delivery. There were no demographic, historical, or behavioral findings significantly associated with premature rupture of membranes or preterm premature rupture of membranes. Toth et al.[16] have suggested that persistent effects of prior endometrial infection may mediate recurrent preterm birth. In our study, a past history of any sexually transmitted disease was linked to occurrence of premature rupture of membranes ($p = 0.06$), but not preterm birth or preterm premature rupture of membranes ($p = 0.1$). History of prior pelvic infection or sexually transmitted disease was commonly reported among our patients (Table I), which may have mitigated any specific effect of prior reproductive tract infection. In addition to possibly persisting reproductive tract infections, it is likely that unrecognized intrinsic or metabolic factors associated with preterm birth may also persist in subsequent pregnancies. Elucidation and elimination of such persistent factors could reduce preterm birth significantly in women at risk.

The numbers and percentages of subjects with various cervicovaginal microorganisms are similar to those found in previous studies of our patients and other urban populations using comparable procedures.[10, 17] The overall inability of study drug to eliminate the microorganisms tested for is likely explained by (1) the lack of erythromycin activity at lower vaginal pH,[18] (2) short duration of treatment (lack of compliance), or (3) lack of treatment of sexual partners.

Cervical infection with *C. trachomatis* was significantly associated with increased risks of premature rupture of membranes and preterm birth, and was recovered more frequently, although not significantly, among women who experienced preterm birth without premature rupture of membranes and preterm premature rupture of membranes. These findings support those of Martin et al.,[19] Harrison et al.,[20] Berman et al.,[21] and Sweet et al.,[22] who also noted associations of *C. trachomatis* genital tract infection with either preterm birth or low birth weight and premature rupture of membranes.

The latter three studies noted increased risks of preterm birth, low birth weight, and preterm premature rupture of membranes only among women who demonstrated antichlamydial IgM antibody, rather than among all women infected with *C. trachomatis*.[20-22] The authors suggested that the presence of specific antichlamydial IgM denoted either recent infection or "invasive" upper genital tract chlamydial infection.[20-22] Subclinical endometritis occurs commonly (>30%) among nonpregnant women with chlamydial cervicitis[23] and may also occur during pregnancy.

Vaginal presence of *U. urealyticum* was associated with subsequent premature rupture of membranes ($p = 0.08$) but not preterm birth ($p = 0.3$). Others have noted increased *U. urealyticum* genital colonization or placental infection among patients with premature rupture of membranes, preterm birth, or both.[24, 25] *U. urealyticum* was the most common microorganism recovered between layers of amniochorion in patients who were delivered before 37 weeks' gestation in a case-controlled study by Hillier et al.[25] Although intrauterine infection with *U. urealyticum* is well described, the frequency of genital infection among women with uncomplicated pregnancy (up to 85%) suggests a complex relationship between *U. urealyticum* infection and abnormal reproductive outcomes. Quinn et al.[26] suggested that certain *U. ureaplasma* serotypes are more likely to be associated with preterm birth. Many strains of *U. urealyticum* produce phospholipase A_1, A_2, and C as well as IgA proteases in vitro.[27] Among our patients, recovery of *U. urealyticum* was the only microbial association noted with high vaginal concentrations of phospholipase C (data not shown). Hillier et al.[25] further suggested that interactions between *U. urealyticum* and other vaginal conditions or microflora may be important in determining the virulence of ureaplasmas.

Vaginal pH >4.5 (detected here by Nitrazine paper) was associated with premature rupture of membranes ($p = 0.03$; relative risk = 2.5) by means of univariate analysis, but not when the presence of other microbiologic conditions were controlled by logistic regression. An association between increased vaginal pH and abnormal pregnancy outcomes was noted by both Minkoff et al.[28] and Ernest et al.[29] Whereas Ernest measured vaginal pH with a special pH meter, both the study by Minkoff et al. and our study used widely available but less accurate pH paper. Vaginal pH itself may alter the lower reproductive tract milieu and, possibly, directly affect processes involved in labor or membrane rupture by some as yet undefined mechanism. Both Minkoff et al.[28] and Ernest et al.[29] suggest that increased vaginal pH is more likely a marker for the presence of abnormal genital tract microfloras, including the presence of bacterial vaginosis, *T. vaginalis*, or both.

In this study bacterial vaginosis (Gram stain diagnosis) was not significantly associated with preterm birth or preterm membrane rupture. However, bacterial vaginosis, presumptively diagnosed by the presence of proline aminopeptidase, was found in four of five women who were delivered at <34 weeks' gestation ($p = 0.04$) (Table III). Similarly, in a prospective study of 233 women, Minkoff et al.[17] were unable to dem-

onstrate a statistically significant association between clinical findings suggesting of bacterial vaginosis and preterm birth or preterm premature rupture of membranes. Minkoff et al.[17] did note increased risk of preterm birth and premature rupture of membranes among women from whom *Bacteroides* species and *M. hominis* (microorganisms commonly associated with bacterial vaginosis) were recovered.

Conversely, other studies found increased risk of preterm labor, birth, or membrane rupture among women with bacterial vaginosis.[30, 31] Differences in the methods used to detect bacterial vaginosis, study design, populations studied, sample size, or true lack of effort could account for such differences.

As previously shown by Toth et al.,[16] vaginal recovery of *S. aureus* was associated with preterm rupture of membranes and preterm birth. Although less frequently isolated than other bacteria, strains of *S. aureus* recovered from the vagina may be powerful producers of collagenases and phospholipases A_2 and C as well as a variety of other possible virulence factors.[4, 5]

Although taken only for relatively few days ($\bar{x}$ = 5 days) by patients in this study, univariate analysis showed that erythromycin treatment was associated with reduced premature rupture of membranes (p = 0.01; relative risk = 0.4; 95% confidence interval = 0.2 to 0.8). Multivariate analysis (Table IV) showed that erythromycin treatment was associated with reduced low birth weight (p = 0.02), premature rupture of membranes (p = 0.01), and possibly preterm birth (p = 0.06). Prior controlled trials of antibiotic treatment during pregnancy used lengthy courses of either tetracycline, erythromycin, or clindamycin, given orally for as long as 6 weeks.[6-8] Elder et al.[6] administered tetracycline (122 patients) versus placebo (109 patients) to inner-city women from 1963 to 1965. They noted longer duration of pregnancy (tetracycline: $\bar{x}$ = 39.1 weeks; placebo: $\bar{x}$ = 38.1 weeks; χ^2 = 2.4) and greater birth weight (tetracycline: $\bar{x}$ = 115.6 ounces; placebo: $\bar{x}$ = 110.8 ounces; χ^2 = 1.7). Premature rupture of membranes was not further defined but occurred in 9.9% of women who received tetracycline versus 12.5% of women treated with placebo (χ^2 = 1.9).

Similar investigations from 1971 to 1980 were done by Kass et al.[7] to evaluate erythromycin or clindamycin administered orally for 6 weeks in comparison with placebo among women with genital tract *M. hominis* or *U. urealyticum* infections. These investigators also noted incomplete compliance; fewer than half the patients completed the treatment protocols. A trend for increased birth weight was noted only if (1) mothers took the study antibiotic for 6 weeks, (2) they demonstrated ≥fourfold increase in titer to *U. urealyticum,* and (3) if the 6-week erythromycin treatment was continued in the third trimester (second trimester; low birth weight: erythromycin, 7%; placebo, 8% versus third trimester; low birth weight: erythromycin, 3%; placebo, 12%; p = 0.063). Despite such intensive treatment, vaginal ureaplasmas or mycoplasmas persisted at follow-up examination, as in our study. Kass et al.[7] suggested that the antibiotic action was directed toward "reducing invasion from the vaginal source," rather than eliminating carriage of vaginal mycoplasmas.[7] Subsequently, Quinn et al.[32] noted that placentas from women who received either erythromycin or doxycycline were rarely infected with mycoplasmas.

In further analysis, McCormack et al.[8] noted that of the various treatments, only clindamycin taken for at least 3 weeks was associated with reduced recovery of *M. hominis;* neither erythromycin preparation nor clindamycin altered recovery of *U. urealyticum.* By means of a one-tailed analysis, McCormack et al. again showed significant increases in birth weight only among women who were deemed to have completed 6 weeks of erythromycin treatment begun in the third trimester (erythromycin, 3330.7 gm; placebo, 3187 gm; p = 0.042). McCormack et al.[8] again suggested that the effects of erythromycin may not be specific for mycoplasmas and that "interactive effects of other agents such as chlamydia, anaerobic bacteria and other agents" should be investigated. As an example of such possible interactive effects, Table III demonstrates the frequency of identified genital infection and conditions among the five women in our study who were delivered at ≤34 weeks' gestation. Four of five had multiple, easily detectable, and potentially treatable vaginal infections or conditions.

How treatment with erythromycin or similar antibiotics might reduce perinatal morbidity remains unknown, but several possibilities exist. As noted, erythromycin possesses antimicrobial activity against a number of microorganisms associated with premature rupture of membranes: *C. trachomatis,* group B streptococcus, *S. aureus,* and mycoplasmas. Although it is relatively inactive at vaginal pH, erythromycin is active at serum pH and achieves uterine tissue concentration approximating maternal serum.[18] Clindamycin, a related antibiotic, also achieves higher concentrations in fetal membranes than in maternal serum.[33] Preliminary information suggests erythromycin is also relatively concentrated in membranes (R. Bowden, PhD, personal communication). Increased concentrations as well as relatively enhanced activity of these antibiotics within amniochorion and surrounding tissue likely inhibit growth or metabolism of susceptible microorganisms. As suggested by McCormack et al.,[8] effective endometrial level concentrations of erythromycin could also reduce ascent of cervicovaginal microorganisms.

Other factors may also play roles in reduction of perinatal morbidity. Much work shows that erythro-

mycin and other antibiotics that interfere with bacterial protein synthesis can suppress or eliminate release of bacterial virulence factors (such as fetal membrane-damaging proteases) even at subinhibitory concentrations.[34] In vitro studies show that both subminimal inhibitory concentrations and supraminimal inhibitory concentrations of erythromycin eliminate bacterial protease induced weakening of fetal membrane preparations and that erythromycin does not alter measures of membrane strength.[34] Correspondingly, in this study effects of erythromycin appeared linked to the presence of specific, erythromycin-susceptible cervicovaginal microflora.

The results of our study support suggestions that maternal genital tract infections or associated inflammatory changes play possibly preventive roles in the pathogenesis of preterm birth in an important number of women.

Short-course treatment with erythromycin base was associated with reduced risks of premature rupture of membranes and low birth weight and possible preterm birth ($p = 0.06$) (multivariate analysis). Erythromycin appeared safe but was not well tolerated, thus empiric erythromycin treatment is not yet recommended. Controlled studies to evaluate the efficacy and safety of focused antimicrobial treatments during pregnancy are under way. Understanding of the mechanisms through which maternal genital tract infection mediate preterm birth awaits further basic and applied microbiologic and immunologic study.

Vitamin E levels in premenstrual syndrome

C. James Chuong, MD, MPH, Earl B. Dawson, PhD, and Edward R. Smith, PhD
Galveston, Texas

To determine whether changes in peripheral vitamin E levels are associated with symptoms of premenstrual syndrome, 10 patients with premenstrual syndrome and 10 control subjects were studied. They gave blood at 2- or 3-day intervals throughout three menstrual cycles. The vitamin E was measured by fluorometry after hexane extraction and luteinizing hormone was measured by radioimmunoassay. In the control group, vitamin E values were 854 ± 45 μg/dl (mean ± SE) during the luteal phase and 925 ± 55 μg/dl during the follicular phase. No significant changes were noted between the two values. In the patients with premenstrual syndrome, the values were 849 ± 53 μg/dl during the luteal phase, which was not significantly different from 858 ± 48 μg/dl during the follicular phase. No significant changes were noted between the control group and the patients with premenstrual syndrome in either the luteal or the follicular phase. Vitamin E deficiency in patients with premenstrual syndrome was not shown by peripheral vitamin E levels in our study. (AM J OBSTET GYNECOL 1990;163:1591-5.)

Key words: Vitamin E, premenstrual syndrome

Many theories have been proposed to understand the pathophysiology of premenstrual syndrome (PMS) in the hope of finding an effective treatment.[1] The Biskinds[2] were the first to propose the role of nutritional factors in PMS. Over the past few years, nutritional supplements have been widely used as a treatment of PMS.[3-6] The use of these supplements is based on the assumption that patients with PMS consume more refined sugar, refined carbohydrates, and dairy products, and less vitamins such as vitamin E than do normal women.[7] The deficiency of vitamin E was suggested to be related to premenstrual symptoms.[8] Excessive and aberrant prostaglandin synthesis have been implicated in the pathogenesis of PMS,[9] and there was some evidence suggesting that vitamin E could modulate the production of prostaglandin. Supplemental vitamin E blocks the age-related increase in prostaglandin E in mice,[10] whereas it reduces the release of arachidonic acid from phospholipids.[11]

There are no valid conclusions on the efficacy of vitamin E in the treatment of PMS, although some investigators reported that vitamin E was an effective treatment for breast tenderness and other PMS symptoms.[12, 13] However, it was noted that the placebo and vitamin E were not administered in a cross-over fashion for each patient, and vitamin E deficiency was never shown in these patients when compared with control subjects. Serum vitamin E levels may assist in the assessment of a vitamin E deficiency in patients with PMS and serve as a guideline before and during vitamin E treatment. Therefore the objective of this study is to determine whether changes in peripheral vitamin E levels are associated with PMS symptoms.

Material and methods

The study was approved by the Institutional Review Board of the University of Texas Medical Branch, Galveston. Ten patients, 24 to 39 years of age, in general good health with regular menses for at least six previous cycles were studied. All were interviewed by the same investigator (C. J. C.) for detailed medical history. All were from a middle-class population in southeast Texas. Interview on the diet history and daily intake of various nutrients did not reveal evidence of extraordinary food intake. Results were normal for physical examinations by either the investigator or the referral physicians within 6 months before the study began. They were in generally good health, and no significant medical conditions from history or on physical examination were noted. They had no history of psychiatric disorders, as determined by the schedule for affective disorders and schizophrenia—lifetime interview.

Before enrollment the patients were instructed to start charting the daily diary on the first day of the menses throughout the entire menstrual cycle after the initial visit and to qualitatively measure premenstrual complaints. The daily diary was designed by us to follow the diagnosis guidelines established by the National Institute of Mental Health. Each patient documented within the last half of the cycle at least three of the 18 symptoms, with at least one psychologic and one somatic symptom for at least one preceding menstrual cycle. The 18 symptoms included irritability; tension or anxiety; mood swings; emotional lability; restlessness; decreased concentration; depression; aggression; poor coordination; craving for sweet or salty food; lethargy; generalized swelling; breast tenderness; abdominal bloating; swelling of the face, hands, or feet, weight gain; headache; and change in bowel habits. Patients were eliminated from the study if the symptoms were present in the first half of the cycle or if the symptoms persisted for more than 2 days after the onset of menses.

Each subject was also instructed to complete the menstrual distress questionnaire[14] on days 7 and 25 of the same menstrual cycle. They also needed to complete the basal body temperature (BBT) chart during the same cycle. All of them showed a biphasic pattern with evidence of ovulation and adequate luteal phase. The menstrual distress questionnaire was described in previous studies.[14] Women whose scores on the questionnaire were >80 on day 7 or <95 on day 25 of the menstrual cycle were excluded from the study. With these entry criteria, the mean score (± SE) on the menstrual distress questionnaire was 55.2 ± 2.3 on day 7 and 125.7 ± 8.2 on day 25.

Ten female volunteers from among our institution's employees served as the control group. They were in general good health and had regular predictable menses. None of them had premenstrual symptoms or severe dysmenorrhea. Subjects were excluded if they had taken any drugs or medication including vitamin or nutritional supplements during the 8 weeks before the study. They were also asked to keep a daily diary and to complete the menstrual distress questionnaire and the BBT chart in the same fashion as the patient group. None of them showed significant premenstrual symptoms on the daily diary. They all showed a biphasic pattern and adequate luteal phase on the BBT chart. The mean score (± SE) on the menstrual distress questionnaire before the study was 53.1 ± 2.6 on day 7 and 51.5 ± 1.1 on day 25.

Informed consent was obtained from all the participants. After an overnight fast the blood samples for vitamin E, luteinizing hormone (LH), and follicle stimulating hormone (FSH) assays were drawn between 8 AM and 10 AM. Before the blood was collected the women sat quietly for 30 minutes. They gave blood at 2- or 3-day intervals, starting on day 1 of the menstrual cycle throughout three cycles. The patients and controls were instructed to complete the menstrual distress questionnaire on days 7 and 25 of the menstrual cycle for three cycles. They were also asked to complete the BBT chart during the same three cycles.

Ten milliliters of blood was collected, permitted to clot, and centrifuged at 1000 *g* for 15 minutes at 24° C. The serum was stored at −20° C until analyzed. The determination of vitamin E levels was by measurement of the ultraviolet fluorescence at 340 nm on activation at 295 nm, the absorption peak for pure α-tocopherol in hexane.[15,16] All glassware used in the procedure was acid-washed (5% nitric acid, rinsed with reagent-grade water, and air-dried). Two milliliters each of reagent-grade water (Milli-Q, Millipore, Bedford, Mass.) and absolute ethanol (redistilled at 82° C) were added with vortexing to denature the serum protein and release α-tocopherol. The free α-tocopherol was extracted by vortexing the serum homogenate with pure hexane (redistilled at 85° C, Fisher Scientific, Houston, Tex.) and centrifugation at 900 *g* for 5 minutes at 24° C. The hexane phase of each tube was transferred by glass pipette to 1 cm quartz cuvettes and the fluorescence measured with a Turner 430 spectrofluorometer (Sequoia-Turner, Palo Alto, Calif.). The serum α-tocopherol levels were determined by the comparison of the fluorescence of the serum hexane extract with the fluorescence of known levels of pure dl-α-tocopherol (Sigma Chemical Co., St. Louis). The results were expressed as μg/dl. The concentrations of standard dl-α-tocopherol solutions in absolute ethanol were from 200 to 2000 μg/dl in 100 μg increments and the fluorescence was linear throughout this range. The purity of the α-tocopherol standard was confirmed by spectral analysis, and the absorption peak of maximum

†Obesity is defined as body weight 20% greater than IBW.

fluorescence was observed at 295 nm excitation with 340 nm emission. A recovery study of 0.3 ml test aliquots of 50% serum pool and 100 μg/dl increments of dl-α-tocopherol in absolute ethanol from 200 through 2000 μg/dl resulted in 94% recovery of the added vitamin.

LH and FSH were measured by double-antibody radioimmunoassay. All reagents except the standards were obtained from the National Hormone and Pituitary Program (Baltimore, Md.). LH and FSH standards were obtained from the World Health Organization. The intraassay coefficient of variation was 7.3% for LH and 6.8% for FSH, whereas the interassay variations were 12.3% and 15% for LH and FSH, respectively.

All samples from the same patient were run in duplicate in the same assay for vitamin E, LH, and FSH.

The day of LH surge was considered as the midpoint of the cycle and was designated day 0. All other measurements were expressed as the number of days before or after the LH surge. The hormonal measurement during the follicular phase (day LH −14 to −3) of each month for each subject was the mean of all data during the follicular phases of each month. The mean of the three months' values for each subject was then obtained. The hormonal measurement during the luteal phase (day LH +3 to +14) was calculated in a similar fashion. The two-way analysis of variance (ANOVA) with the use of general linear models from SAS[17] was used to test for significant intragroup changes of vitamin E levels between the follicular and luteal phases. Comparisons between the control group and the group with PMS during the follicular and luteal phases were also made by ANOVA. The differences in the menstrual distress questionnaire scores were determined by the two-sample or paired-sample Student *t* test. The level of significance was $p < 0.05$.

Results

There were no differences in age, body weight, marital status, reproductive history, menstrual history, or degree of dysmenorrhea between the patient and control groups (Table I). The mean duration of PMS symptoms in the patient group was 60.5 months.

To participate in the study, the menstrual distress questionnaire score on day 7 had to be <80. The questionnaire score on day 7 before the study for the group with PMS was not significantly different from that of control subjects (55.2 ± 2.3 vs 53.1 ± 2.6, mean ± SE). The large difference in menstrual distress questionnaire score on day 25 (125.7 ± 8.2 for the group with PMS and 51.5 ± 1.1 for the control group) was expected, on the basis of the criteria for inclusion in

F, Follicular phase; *L*, luteal phase; numbers in parentheses are number of observations.

this study. A similar pattern of score changes were noted in each PMS and control subject each month during the study period. The mean of the 3 months' scores for the patients with PMS was 53.1 ± 1.9 during the follicular phase and 120.7 ± 6.2 during the luteal phase. For the control group, the mean was 49.8 ± 2.6 during the follicular phase and 52.8 ± 2.4 during the luteal phase.

All the participants showed a biphasic BBT pattern each month, suggesting ovulation and adequate luteal phase. The LH and FSH levels are shown in their characteristic patterns, with the day of the LH peak designated as day LH 0. The LH peak reached 92.3 ± 12.5 mIU/ml (mean ± SE), whereas FSH was 24.2 ± 5.3 mIU/ml on day LH 0. In the control group, vitamin E values were 854 ± 45 μg/dl (mean ± SE) during the luteal phase, and 925 ± 55 μg/dl during the follicular phase. No significant changes were noted between the two values. In the patients, the values were 849 ± 53 μg/dl during the luteal phase, which was not significantly different from 858 ± 48 μg/dl during the follicular phase. No significant changes were noted between the control group and the patients in either the luteal or the follicular phase (Table II).

Comment

It was hypothesized that vitamin E exerted its clinical effects on PMS symptoms through regulation of aberrant prostaglandin synthesis.[13] This was determined on the basis of the observation that there was an inhibitory effect of vitamin E on the release of arachidonic acid from its storage pool, which decreased the availability of prostaglandin $F_{2\alpha}$ precursors. The effect of vitamin E on the PMS symptoms was also hypothesized to be related to its modulatory effects, either directly or indirectly, on neurotransmitters in the central nervous system. Vitamin E supplementation blocked decreases γ-aminobutyric acid induced by prostaglandin precursors.[18] Radiolabeled vitamin E crossed the blood-brain barrier into several areas in the central nervous system in rat.[19] Vitamin E deficiency was associated with decreases in α-adrenergic binding sites in the central nervous system and decreases in choline acetyltransferase.[20]

However, vitamin E deficiency in PMS patients was not shown by peripheral vitamin E levels in our study. Our findings cannot explain the beneficial effect of vitamin E in PMS patients in previous double-blind studies.[12, 13] Those patients were assumed to have vitamin E deficiency before the treatment was given. The dosages of vitamin E administered to these patients ranged from 150 to 600 IU/day, which was 500% to 2000% of the U. S. recommended daily allowance for adults. We suggest that the response to vitamin E in these studies was a result of a pharmacologic response rather than correction of a deficiency state.

Another explanation for this discrepancy might be that vitamin E levels in the peripheral blood do not parallel those in the central nervous system. It remains possible that the bioavailability of vitamin E in the central nervous system, which is related to the activities of several neurotransmitters, could decrease during the luteal phase in some patients with PMS. As a result, the premenstrual symptoms occur. However, these changes in vitamin E levels in the central nervous system may not be reflected in the peripheral blood levels.

The procedures we used to measure serum vitamin E levels were described by Duggan[15] followed by Hansen and Warwick.[16] The same method has been used by several investigators.[21-23] In one study[22] The lower vitamin E levels in the peripheral blood of subjects with sickle cell anemia increased to the values similar to that of normal subjects after they were treated with vitamin E. It would be interesting to see whether our patients

with PMS will have increases of vitamin E levels in the peripheral blood and whether they will have decreases of symptoms after the vitamin E is supplemented.

Because of the rigorous initial entry criteria, such as at least a 2-month medication-free (including any form of vitamin or nutritional supplement) interval before testing, and the requirement of blood drawing at 2- or 3-day intervals for 3 months when no treatment could be given, the sample size in our study was limited. Yet these subjects would be expected to show vitamin E deficiency during the luteal phase if the deficiency is related to PMS symptoms, and can be shown in the peripheral circulation.

Mira et al.[24] measured several vitamin and trace element levels in the serum of patients with PMS on two occasions (premenstrual and postmenstrual) in 1 month and found no evidence for nutritional deficiencies including vitamin E. We now confirm and enlarge this previous observation. Further clarification of the role of vitamin E in central neurotransmitter activities and the relationship between the central and peripheral levels of vitamin E is needed. Until these issues are addressed, vitamin E supplementation can only be considered as an empirical therapy for PMS.

We thank Ms. Jo Ann Rabb for excellent editorial assistance in the preparation of the manuscript, as well as Elaine Brown, Michael Harris, William A. Harris, BA, and Sheila Jones for technical assistance.

Intrauterine *Listeria* infection: Prenatal diagnosis by biophysical assessment and amniocentesis

Robert I. Liner, MD
San Francisco, California

Diagnosis of intrauterine listeriosis and fetal salvage were facilitated by amniocentesis in a nonlaboring patient with fever and decreased fetal movement at 35 weeks' gestation. (AM J OBSTET GYNECOL 1990;163:1596-7.)

Key words: Amniocentesis, biophysical assessment, listeriosis

Maternal listeriosis is known to be associated with a minimum of clinical symptoms but a high degree of perinatal mortality and morbidity. We report a case in which biophysical assessment for decreased fetal movement prompted amniocentesis in a nonlaboring, minimally ill patient at 35 weeks' gestation. Microscopic analysis of the fluid facilitated a prenatal diagnosis of fetal sepsis as a result of *Listeria*, allowing immediate initiation of antibiotic therapy, cesarean delivery, and fetal salvage.

Case report

Our patient was a 30-year-old woman, gravida 4, para 0, at 35 weeks' gestation. Three days after a reactive nonstress test—performed because of an episode of vaginal bleeding with a low-lying placenta—she called to report an absence of fetal movement over the past 12 hours. She had not bled again but reported malaise, increased flatulence, and mild gas pains. She had not noticed fever, chills, or contractions.

On examination she seemed anxious but not ill. She was surprised to hear that she had a fever of 38.6° C. The pharynx was slightly erythematous. The abdomen was benign. The uterus was soft, nontender, and nonirritable. There were no contractions. Fetal heart activity was monitored at a rate of 160 beats/min without decelerations. Variability was present but diminished. Her cervix was long and closed; the vertex was ballotable.

The report of absent fetal movement and the decreased variability led to biophysical assessment. Despite rapid infusion of a liter of dextrose in 5% lactated Ringer's solution, the fetus appeared inert; two points were given for fluid and two for cardiac activity for a score of 4.

Unexplained maternal fever and verified lack of fetal activity suggested the possibility of sepsis, so the biophysical assessment was followed by amniocentesis. We obtained clear fluid with a striking yellowish green color. An immediate microscopic examination of stained and prestained fluid disclosed 4+ Gram-positive rods with a tumbling motility characteristic of *Listeria monocytogenes*. Because of ampicillin allergy, the patient was started on intravenous erythromycin while preparations were made for operative delivery. The intensive care nursery was advised of the probability of fetal listeriosis and, because of the evidence of fetal distress, general anesthesia was induced and the patient was promptly delivered of the infant.

Approximately 1 hour after the mother's hospital admission, a shocky 2200 gm female was delivered with Apgar scores of 2 and 4 at 1 and 5 minutes, respectively. The hematocrit was unremarkable. Cord blood was acidotic: pH (venous), 7.21; P_{CO_2}, 52; and P_{O_2}, 23. A dopamine drip was required to maintain the infant's blood pressure for the first 18 hours after birth. Ventilatory support was required for 28 hours. Cultures of maternal blood, amniotic fluid, fetal blood, and fetal gastric aspirate were positive for *Listeria;* the fetal cerebrospinal fluid was culture negative. The placenta, in addition to acute chorioamnionitis, had microabscesses typically associated with *Listeria* placentitis.

The mother had a benign postoperative course. She was discharged on postoperative day 4. The infant received a 2-week course of ampicillin combined with 1 week of gentamicin and has been entirely well since discharge 2 weeks after delivery.

Comment

Listeriosis in human beings occurs primarily in circumstances of altered immunity, including pregnancy. Because maternal symptoms are vague and nonspecific, they are easily dismissed as influenza. For that reason, diagnosis is generally not made until the patient is in labor or, more often, until after the delivery of a sick neonate. In such cases of congenital listeriosis, the mortality has been reported to be as high as 71%.[1]

Among the few cases in which maternal *Listeria* infection has been specifically diagnosed and treated prenatally, the organism has most often been recovered

from maternal blood or from the cervix. Amniocentesis has been recommended in midtrimester in the evaluation of otherwise unexplained maternal fever. A recent case report documents a third-trimester case of congenital listeriosis in which amniocentesis was performed in the context of uterine irritability and a threatening cervix at 32 weeks' gestation.[2] But we are not aware of any reported case in which a prenatal diagnosis of *Listeria* sepsis has resulted from amniocentesis prompted by lack of fetal movement. Our case serves to illustrate the point that reduced fetal activity may be a sign of amnionitis and fetal sepsis even in the absence of either contractions or other signs to suggest uterine infection.

Pregnancy outcomes among mothers infected with human immunodeficiency virus and uninfected control subjects

Howard L. Minkoff, MD,[a] Cassandra Henderson, MD,[b] Hermann Mendez, MD,[c] Mitchell H. Gail, MD, PhD,[d] Susan Holman, RN, MS,[e] Anne Willoughby, MD,[f] James J. Goedett, MD,[g] Arye Rubinstein, MD,[h] Pamela Stratton, MD,[e] Judith H. Walsh,[i] and Sheldon H. Landesman, MD[e]

Brooklyn and Bronx, New York, and Bethesda, Maryland

Between June 26, 1985, and Feb. 24, 1989, 101 seropositive pregnant women and 129 seronegative pregnant women from the same prenatal clinics in Brooklyn and the Bronx were recruited into a prospective study of human immunodeficiency virus infection in pregnant women and their offspring. This report details the course of pregnancy and short-term neonatal outcomes of 91 seropositive women and 126 seronegative women who gave birth during the study period. Seropositive mothers were significantly more likely to have sexually transmitted diseases (17.6% vs 7.1%, $p = 0.017$) and medical complications (43.0% vs 25%, $p = 0.006$) during pregnancy. No other obstetric complications (e.g., chorioamnionitis, endometritis, toxemia, or placental problems) were associated with serologic status. After controlling for confounding variables (drug use, tobacco use, age of mother, and clinic), we found that the mother's serologic status was not significantly associated with birth weight, gestational age, head circumference, or Apgar scores among live infants. For example, after adjustment on confounders we found that children born to seropositive mothers weighed about 7 gm more than children of seronegative mothers (95% confidence interval, −180 to 194 gm). We conclude that in this population human immunodeficiency virus infection has little demonstrable impact on the status at birth of live neonates. (Am J Obstet Gynecol 1990;163:1598-604.)

Key words: Human immunodeficiency virus, pregnancy outcomes, sexually transmitted diseases

Anonymous newborn surveillance programs have provided estimates of human immunodeficiency virus (HIV) serologic prevalence among pregnant women in various parts of the United States.[1-3] In New York state, for example, where one of the most comprehensive programs has been instituted, 0.66% of neonates are born with passively transferred maternal HIV antibody in the blood.[1] Programs in Massachusetts have revealed that 0.75% of neonates in inner-city hospitals are similarly exposed to HIV.[2] Studies in more than 44 states, similar to the investigations conducted in New York and Massachusetts, result in estimates that >5000 HIV-infected women give birth annually in the United States. Coincident with the recognition of this problem, prenatal HIV counseling and testing programs have been recommended by a variety of agencies (including the Centers for Disease Control[4] and the American College of Obstetricians and Gynecologists[5]) and have been instituted in many prenatal centers.[6, 7] Information necessary to appropriately counsel and manage women identified as seropositive includes data on the short-term outcome of pregnancy. To date, published results from studies analyzing the effect of HIV infection on pregnancy outcomes (aside from those performed in Africa where some unique factors present in these populations influence birth outcomes) have been limited by failure to control for potential significant confounders, such as alcohol and tobacco use, and

inclusion (almost exclusively) of intravenous drug users.[8, 9] In addition, previous reports from developed nations have analyzed only 25 to 30 births to seropositive patients with a concomitant limitation in the statistical power of results.[8, 9] Finally, recent data on the effect of maternal serologic status on birth outcomes[10] have been in conflict with initially reported data.[8, 9]

To address these and other concerns, we undertook a prospective study of HIV-positive pregnant women (predominantly asymptomatic) and their offspring and comparable HIV-negative women from the same clinics. Although this cohort study is designed to provide information on the natural history of HIV disease in mothers and children for several years after an index pregnancy, this report is restricted to a comparison of the health status at birth of infected and uninfected mothers and their infants.

Methods

Population. From June 26, 1985, to Feb. 24, 1989, HIV-infected and uninfected prenatal patients at clinics in Brooklyn and the Bronx were recruited into a prospective cohort study. Except at the Kings County Hospital Center's clinic for prenatal Haitian women (see below), all women who agreed to be tested for HIV and who agreed to remain in follow-up through pregnancy and to allow subsequent follow-up of themselves and their infants were included in the study (Table I). Thirty of 77 patients at the Kings County Hospital Addictive Disease Clinic (Brooklyn Addictive Service in Table I) were seropositive. Referred patients in Brooklyn (outside referrals) who came for HIV testing and were found to be HIV positive, were recruited as were seronegative patients from the same source (20.6% of these patients are drug users). At Jacobi Hospital and Bronx Lebanon Hospital in the Bronx, prenatal patients with recognized risk for HIV infection (i.e., intravenous drug use or sexual partner of drug user) were referred by clinic staff to study personnel and offered HIV testing. All such referrals (seropositive and seronegative) were offered study entry. Because only about 6% of women at the Kings County Hospital Center's Prenatal Clinic for Haitian women were seropositive, only two seronegative women were selected for each seropositive woman at this clinic. The seronegative women who were selected to enter the study were in the same trimester of pregnancy as the seropositive women at entry. Unregistered patients were not evaluated in this study.

Data are available on 101 seropositive patients and 129 seronegative patients who consented to entry the study. An additional 11 seropositive women refused entry or never returned for results. All participants completed their pregnancies or, in the case of abortions, have passed their estimated dates of confinement. Among seronegative patients, 124 (96%) had live births, 2 (2%) had stillbirths, and 3 (2%) underwent intentional abortion. Among seropositive patients, 91 (90%) had live births, one had a spontaneous abortion, and 9 (9%) had intentional abortions. This study focuses on the 91 HIV-seropositive and 126 HIV-seronegative mothers who gave birth and for whom outcome data are available. Twins born to two of the HIV-seropositive mothers and stillbirths born to two seronegative mothers were excluded from infant evaluations. The mothers of twins were also excluded from analyses of obstetric complications.

Outcome measures. Obstetric outcomes were defined as follows: premature rupture of membranes, rupture of membranes before the onset of labor (since women undergoing electively scheduled cesarean section were at less risk for premature rupture of membranes, they were excluded from this analysis); maternal fever, two temperature readings of $\geq 101°$ F during the intrapartum or postpartum period; chorioamnionitis, women in labor with a temperature $>100.4°$ F without an extrauterine cause. Because some patients were uncertain about their last menstrual period and

some patients did not have early ultrasonographic evaluation, gestational age was based on physical examination at birth. In addition, standard physical measurements and Apgar scores were recorded at birth.

T-cell analyses. Lymphocyte phenotyping on a flow cytometer (Epics C, Coulter Electronics, Inc., Hialeah, Fla.) was performed with directly fluoresceinated monoclonal antibody reagents OKT4 and OKT8 (Ortho Diagnostics, Raritan, N.J.) as phenotypic markers of $T4^+$ and $T8^+$ T-lymphocyte subsets, respectively. Absolute T-cell counts were the product of the proportion of cells staining with each marker and the total lymphocyte count as measured by complete blood count and differential.

Statistical methods. Quantitative variables were compared with a two-sample t test, and proportions were compared with a χ^2 test unless any cell count was <5; then two-sided Fisher's exact test was used. Significant levels were adjusted using the procedure of Mantel and Haenszel[11] for stratified analysis of contingency tables. Adjusted estimates of HIV effects on birth weight and other infant birth characteristics were obtained from multivariate linear regressions that included HIV status (1 if seropositive, 0 otherwise) and additional covariates that affect fetal growth. The symbol NS indicates that a difference is not statistically significant ($p > 0.05$).

Results

Women. Infectious, obstetric, and medical complications are detailed in Table II. Seropositive patients had significantly more (17.6%) sexually transmitted diseases than seronegative patients (7.1%). Chorioamnionitis, endometritis, and maternal fever occurred among 2 (2.4%), 4 (4.4%), and 12 (14.3%) of the seropositive women and 6 (5.0%), 3 (2.4%), and 11 (9.2%) of the seronegative women, respectively (NS). None of these differences was statistically significant in a stratified analysis to control for delivery by cesarean section (the cesarean section rates for seropositive and seronegative patients were 12% and 18%, respectively). Other infectious complications (e.g., urinary tract infections, respiratory infections) occurred in 9 (9.9%) seropositive women and 5 (4.0%) seronegative women (NS). There were three opportunistic infections included among the seropositive women's infections (described in detail in a previous publication[12]).

Premature rupture of membranes occurred in 21 of 109 (19.3%) seronegative patients and 25 of 80 (31.2%) seropositive patients (NS); this analysis excludes patients who had elective cesarean sections. No additional obstetric complications, including placental problems, malpresentations, toxemia, or hemorrhage, were associated with serologic status.

Medical complications were noted in 37 (43.0%) seropositive and 30 (25.0%) seronegative woman ($p = 0.006$). Although the total number of complications was greater among seropositive patients, no specific type of complication (e.g., hypertension or diabetes) was significantly associated with serologic status.

Infants. Birth outcomes are shown in Table III. The mean gestational age (± SEM) and birth weight of children of seronegative mothers are 38.8 ± 2.3 weeks and 3014 ± 676 gm compared with 38.2 ± 2.6 weeks and 2906 ± 657 gm for children of seropositive mothers (NS). There was no significant difference when all infants or only those whose mothers had the same drug use status were compared. Similarly, weight/age ratios, heights, and head circumferences did not differ significantly. The mean 1- and 5-minute Apgar scores of children of seronegative mothers were 7.7 ± 1.7 and 8.7 ± 1.1, whereas for children of seropositive mothers the scores were 7.6 ± 1.9 and 8.7 ± 1.2 (NS).

Multivariate linear regression models were used to adjust all analyses in Table IV for site of clinic and mother's prenatal drug status. In addition, mother's cigarette use and age at delivery were inversely associated with birth weight, height, and head circumference and were included in the regression analyses of those outcomes. The last column indicates which covariates were included in the regression models, in addition to HIV serologic status (coded 1 or 0); the coefficients provide an indication of the degree to which the covariates influence the response and in what direction. For example, the number −389 in the birth weight row indicates that mothers who smoke >20 cigarettes per day have infants weighing 389 gm less than infants of nonsmokers. The purpose of this multivariate regression was not primarily to estimate the impact of covariates such as smoking, but to yield a valid comparison between HIV-positive and HIV-negative mothers, even if important characteristics, such as heavy smoking, tended to be more prevalent in one group of mothers than the other. Other covariates (e.g., alcohol use) were considered for inclusion in these models but were not used because they were not statistically significantly associated with birth outcomes in models containing clinic and drug use status.

Table IV shows that maternal HIV status was not significantly associated with size, birth weight, head circumference, or Apgar score in these analyses. The adjusted effect of positive maternal HIV serologic status (± 1.96 SE) was 7.15 ± 187 gm on birth weight, −0.045 ± 1.10 cm on height, and −0.085 + 0.684 cm on head circumference. Additional models adjusting for the effect of maternal T_4-cell level (measured within 2 months of birth) in addition to the factors cited above

*Significance levels were adjusted by stratification on drug use with the procedure of Mantel and Haenszel.

†Sexually transmitted diseases include syphilis, gonorrhea, hepatitis, herpes, condyloma, and genital ulcers diagnosed during pregnancy.

‡No difference noted when each mode of delivery was studied individually (i.e., vaginal, elective cesarean, nonelective cesarean).

§Other infections include respiratory tract, urinary tract, *Candida*, etc.

did not reveal any significant associations between serologic status and birth outcomes. Regression models restricted to only those infants with birth weights <2500 gm and to infants born at <37 weeks' gestation were also performed and revealed no significant associations with serologic status.

To assess the effect of more advanced immunodeficiency on outcomes, we separately assessed women whose last T_4-cell level before delivery was <300/mm³. There were only five such women, however, and their outcomes did not vary significantly from those of other seropositive women.

Comment

Our data indicate that maternal serologic status in a population of women with low acquired immunodeficiency syndrome (AIDS) prevalence (approximately 3% of the seropositive women had AIDS) has little or no demonstrable impact on the course of pregnancy or on the size, weight, and Apgar scores of live neonates. These findings are in agreement with those of Selwyn et al.,[9] who studied American women who used drugs, and with those of Johnston et al.[8] who studied women drug users in Edinburgh. Our findings extend those of previous studies by including seropositive women without a history of drug abuse. However, it should be mentioned that the power of the study to detect adverse effects of HIV infection on infrequent complications of pregnancy, such as endometritis or toxemia (Table II) is limited, and additional data on such infrequent complications would be useful.

These results differ from the report of Ryder et al.[10] who found that children born to seronegative women in Zaire weighed 3107 gm, on average, compared with 2888 gm for children of seropositive women. However, most of this difference of 219 gm is attributable to the 85 women with AIDS (18.2% of seropositives) whose children weighed only 2698 gm on average. In contrast, only 3% of the seropositive women in our study had AIDS at the time of delivery. Possibly, as advanced stages of immunodeficiency and AIDS develop in more women in the United States, the effects of seropositivity

*Size is coded as follows: 1 = small for gestational age; 2 = at gestational age; 3 = large for gestational age.

†This ratio is calculated from Fig. 7-1 in Phibbs RH. The newborn infant. In: Rudolph AM, Hoffman, JIE. eds. Pediatrics. Norwalk, Connecticut: Appleton & Lange, 1987. The ratio is (weight − 2.289)/(age − 34) where weight is in kilograms and age is in weeks of gestation.

seen in Africa will become apparent. There are at least two mechanisms by which advanced maternal immunodeficiency could lead to low birth weight. First, the mother's health may suffer and she may be unable to provide an optimal environment for fetal growth. Second, immunodeficiency in the mother might promote direct viral infection in the fetus.[10] The differing results found in Africa may also reflect other aspects of the health of women there, including variations in virulence of HIV strains, social factors, and other causes of low birth weight, such as use of tobacco and drugs. All patients in our study had "wanted" pregnancies (i.e., they chose not to abort). Another possible contributor to the African findings is the fact that 71% of cases were from a hospital serving a lower socioeconomic clientele, whereas only 56% of controls were from that hospital.

Although our data give no indication that seropositivity is associated with birth outcome, the confidence intervals are broad enough to include some deficits (Table IV). For example, the 95% confidence interval for birth weight is −180 to 194. Thus the data do not rule out the possibility that seropositivity induces a deficit of 180 gm. However, larger deficits are not consistent with our data.

As expected, we found that birth weights were related to drug use and smoking as well as maternal age. After including these factors in regression models, as well as T_4-cell counts, and clinic setting, we found no significant effect of serologic status on birth weight or gestational age. The lack of a significant effect of positive serologic status on weight, height, or gestational age may not be generalizable to populations of women with more advanced immunodeficiency, as discussed previously.

We did note a trend toward more frequent infectious complications among seropositive women. Sexually transmitted diseases were diagnosed almost twice as often among seropositive women. This could reflect a life-style that predisposes to both HIV infection and the acquisition of other sexually transmitted diseases, an enhanced susceptibility to HIV infections among patients with sexually transmitted diseases, or a more protracted course of sexually transmitted diseases among HIV-infected women, leading to an increased likelihood of diagnosis of sexually transmitted diseases

*All analyses were adjusted for clinic and mother's prenatal drug use status. Mother's smoking status and age at delivery were associated with birth weight, height, and head circumference and were included in the analysis of these outcomes. The four patients from Bronx Clinic were not included. Dummy variables coded 1.0 or 0.0 indicated referral from the outside, Haitian, or Einstein clinics, whether the mother used drugs, and whether the mother smoked 1 to 19 cigarettes per day or at least 20 cigarettes per day during the first trimester. Mother's age at delivery was coded in years. Size is coded as in Table III. Additional models for the mother's last known thyroxine level, as well as the above factors, were performed but did not result in any significant associations with birth outcomes.

at any given point in time. The association of HIV with sexually transmitted diseases in pregnancy has clinical consequence because many of these infections, particularly syphilis and chlamydia, can lead to perinatal morbidity. Therefore assiduous screening for sexually transmitted diseases at first contact and again in the third trimester seems prudent. Since the efficacy of standard therapies for sexually transmitted diseases in seropositive pregnant women remains largely unstudied, it would seem appropriate to obtain tests of cure. The trend toward a higher incidence of premature rupture of membranes among seropositive women could also reflect a change in vaginal flora that has been linked to premature rupture of membranes.[13]

As expected, opportunistic infections were seen only in the seropositive cohort. A previous report from an overlapping cohort has shown that, as in nonpregnant patients, low T_4-cell counts are predictive of risk for infections among seropositive pregnant women.[12] That report noted a substantial risk of serious infections during pregnancy among those whose T_4-cell counts decreased to $<300/mm^3$. However, opportunistic infections were uncommon among our seropositive patients. Although rare, these serious infections carry potentially devastating consequences for mother and child. However, with the newer treatment modalities, such as aerosolized pentamidine, it may be possible to postpone clinical illness beyond pregnancy. Thus it would be useful to find markers to identify the subset of patients at highest risk for opportunistic infections.

The pregnancy outcomes in these women were more influenced by drug use and smoking than by detectable viral effects. No clinically significant differences in birth weight, birth height, head circumference, or Apgar scores were related to maternal serologic status. Therefore it seems that in populations of relatively healthy seropositive pregnant women both those offspring who will eventually become infected with HIV and those who will not become infected can benefit from the application of conventional precepts of prenatal care. In particular, every effort should be made to encourage the prospective mother to stop using drugs, cigarettes, and alcohol and to reduce exposures to sexually transmitted diseases. In addition, obstetricians should direct increased attention to screening for sexually transmitted diseases, to treatment of these infections, and to

careful posttreatment assessment of the mother's infection status.

Screening for trisomy 21 with ultrasonographic determination of biparietal diameter/femur length ratio

Gerald P. Marquette, MD,[a] Marc Boucher, MD,[a] Micheline Desrochers, RN,[b] and Louis Dallaire, MD[b]

Montreal, Quebec, Canada

Ultrasonographic determination of biparietal diameter/femur length ratios performed at 16 or 17 weeks' gestation in fetuses with trisomy 21 were not statistically different from those of 155 normal fetuses. It appears that this test could not be used for screening for trisomy 21. (Am J Obstet Gynecol 1990;163:1604-5.)

Key words: Ultrasonography, trisomy 21

Lockwood et al.[1] have suggested that Down syndrome may be associated with shortened femur lengths and elevated biparietal diameter/femur length ratios. These features would allow for a noninvasive screening technique applicable to a larger obstetric population than that of patients 35 years old or older. Recently we have had many consultations for ultrasonography on the basis of these skeletal features requesting use of the ratio to rule out trisomy 21 in women not considered at increased risk by maternal age. The concern about offering amniocentesis to such patients for fetal karyotyping motivated this study.

Methods

This cohort study comprised 31 fetuses with trisomy 21 and 155 control fetuses without anomalies. The subjects were drawn from our antenatal genetic diagnostic clinic population. All pregnancies were referred for advanced maternal age ≥35 years. All ultrasonographic and amniocentesis techniques were performed at 16 or 17 weeks by the same team over a period of 3½ years. All ultrasonographic data were gathered with a Siemens Sonoline SL-2 or AC unit with a linear array 3.5 MHz transducer. The biparietal diameter was measured from a leading edge to a leading edge in a transaxial plane of the widest portion of the skull with the thalamus positioned in the midline. The femur was measured along the long axis of the diaphysis, disregarding the curvature. Control subjects were defined as the next five pregnancies after the diagnosis of trisomy 21 in a fetus with the same maternal age and parity, with no chromosomal or anatomic anomaly. As reported by Lockwood et al.,[1] we used a threshold of abnormality for the biparietal diameter/femur length ratio >1.5 SDs above the mean. A 2 × 2 contingency table was constructed for χ^2 analysis with Yates' correction.

Results

There was no significant difference for maternal age, parity, and gestational age at amniocentesis between both groups. The population studied was 92% white and was comparable in both groups. There were 6% blacks and 2% other races. Table I depicts the results in a 2 × 2 table of biparietal diameter/femur length ratio. There was no correlation between the diagnosis of trisomy 21 and an abnormal biparietal diameter/femur length ratio ($\chi^2 = 0.052$, $p = 0.82$).

Table I. Biparietal diameter/femur length ratios in fetuses with trisomy 21 and normal fetuses

Biparietal diameter/femur length	*Trisomy 21*	*Normal*
>1.5 SD	3	14
≤1.5 SD	28	141

$\chi^2 = 0.052$; $p = 0.82$.

Comment

Lockwood et al.[1] demonstrated a sensitivity of 70% with a threshold of 1.5 standard deviation above the mean for biparietal diameter/femur length ratio in a Boston population. In a New Haven population described in the same report the sensitivity was 51%. These authors further added that the positive predictive value of this test was greater than that of screening that is based on maternal age. Our report is a cohort study with matched controls, thus only the sensitivity can be reported; it was 10%. This figure varies greatly from 51% and 70%. Our population probably differs from both Boston and New Haven, but the biparietal diameter and femur length measurements in our study appear similar to previously published tables and cannot explain our different findings.

We conclude that the biparietal diameter/femur length ratio is not a suitable method for screening for trisomy 21 in our population. A recent report[2] on low maternal serum α-fetoprotein values as a screen for trisomy 21 seems more promising but remains to be confirmed in further studies.

Direct analysis of uncultured cytotrophoblastic cells from second- and third-trimester placentas: An accurate and rapid method for detection of fetal chromosome abnormalities

Lee P. Shulman, MD,[a] Avirachan T. Tharapel, PhD,[b] Carole M. Meyers, MD,[a] Owen P. Phillips, MD,[a] Joe Leigh Simpson, MD,[a] and Sherman Elias, MD[a]
Memphis, Tennessee

Transabdominal chorionic villus sampling can be readily used for detection of fetal chromosome abnormalities in the second and third trimesters of pregnancy. Although culture of chorionic villi offers little advantage over cultured amniotic fluid cells with respect to time required to obtain results, cytogenetic analysis of chorionic villi by direct analysis of uncultured cytotrophoblastic cells offers clear advantages because of the very short time required to obtain results. To determine whether direct analysis of uncultured cytotrophoblastic cells from second- and third-trimester placentas can routinely provide rapid and accurate assessment of fetal status, we evaluated chorionic villus specimens obtained from 57 placentas; 49 placentas were sampled in the second trimester whereas eight were sampled in the third trimester. Direct preparations yielded karyotypes in 56 (98.2%) preparations; all results of direct analyses were available within 72 hours and, when requested, within 12 hours. All results were confirmed by chromosome analysis of cultured mesenchymal core cells or cultured fetal tissue. We conclude that direct analysis of cytotrophoblastic cells from second- and third-trimester placentas is a very rapid and accurate method for determining fetal chromosome status that is comparable with, if not superior to, percutaneous umbilical blood sampling. (Am J Obstet Gynecol 1990;163:1606-9.)

Key words: Prenatal diagnosis, chorionic villi, cytogenetics, second and third trimester

Transabdominal chorionic villus sampling can be used to detect fetal chromosome abnormalities in the second and third trimesters of pregnancy.[1-7] Although culture of chorionic villi (mesenchymal core) offers relatively little advantage over cultured amniotic fluid cells with respect to time required to obtain results, cytogenetic analysis of chorionic villi is also possible by the so-called direct analysis of uncultured cytotrophoblastic cells. Direct analysis of uncultured cytotrophoblastic cells provides a rapid assessment of fetal chromosome complement in the first trimester,[8,9] with results available within hours if needed. This interval is potentially even shorter than the 48 to 72 hours required to obtain cytogenetic results from fetal blood samples obtained by percutaneous umbilical blood sampling[10] because direct analysis can be obtained the same day if necessary. We reasoned that direct cytogenetic analysis of cytotrophoblastic cells could offer substantial advantage over other methods used for second- and third-trimester prenatal diagnosis (e.g., cultured amniotic fluid cells, cultured lymphocytes obtained by fetal blood sampling). This article reports our cytogenetic experience with 57 chorionic villus samples, obtained by either transabdominal chorionic villus sampling or pregnancy termination during the second and third trimesters of pregnancy.

Material and methods

Chorionic villus specimens were obtained during a 22-month period (1988 to 1989) from patients undergoing either transabdominal chorionic villus sampling during the second or third trimester (≥14 weeks' gestation) or second trimester (14 to 24 weeks' gestation) pregnancy termination. Gestational age was determined by the patient's last menstrual period and was confirmed by ultrasonographically derived biometric measurements. The entire villus specimen was used if chorionic villi were obtained by transabdominal chorionic villus sampling; 15 to 20 mg of chorionic villi was obtained for cytogenetic analysis from second-trimester pregnancy termination placental specimens; this amount was comparable with amounts we

routinely obtain by transabdominal chorionic villus sampling.

Villi were cleaned and incubated in complete medium (α-minimum essential medium supplemented with 15% Chang medium, 15% fetal bovine serum, 100 IU/ml penicillin, and 100 μg/ml streptomycin) at 37° C for 3 to 15 hours. The incubation time period was determined on the basis of need for rapid (<12 hours) cytogenetic results and the time of day the sample was received in the laboratory. All chorionic villi were treated simultaneously with trypsin–ethylenediaminetetraacetic acid to separate cytotrophoblastic cells from mesenchymal core and with Colcemid to accumulate metaphases.[11] Cytotrophoblastic cells were detached from chorionic villi by vigorously agitating villi with a Pasteur pipette, resuspension in complete medium, and centrifugation at 1000 rpm for 6 minutes. The supernatant was discarded and the pellet was resuspended in 5 ml hypotonic (1 : 1 mixture of 0.075 mol/L potassium chloride and 0.8% sodium citrate) solution. Cells were subsequently fixed thrice with a 3 : 1 methanol:glacial acetic acid solution. Slides were then prepared and stained with Giemsa by conventional methods.

Remaining pieces of villi, which represent portions of mesenchymal core, were used to initiate culture analyses.[11] When fetal tissue (e.g., blood, skin) was available, culture analyses were initiated to corroborate direct cytogenetic results. Conventional tissue culture techniques were used to perform culture analyses of fetal tissues.

Results

Chorionic villus specimens were obtained from 57 subjects. Ten women had undergone transabdominal chorionic villus sampling for genetic diagnosis at or after 18 weeks' gestation (range, 18 to 37 weeks). Of those who had transabdominal chorionic villus sampling, eight women were in the third trimester. In all 10 transabdominal chorionic villus sampling cases, chorionic villus samples were obtained after a single ultrasonographically guided passage of an 18-gauge spinal needle. There were no complications (infection, hemorrhage, stillbirth) among these 10 women who had second- and third-trimester transabdominal chorionic villus sampling. Forty-seven subjects underwent second-trimester (range, 14 to 24 weeks) pregnancy termination for elective or genetic (e.g., fetal chromosome abnormalities, neural tube defects) indications.

Sufficient tissue (≥5 mg of chorionic villi) to initiate both direct and culture cytogenetic analyses was available from all 57 specimens. Transabdominal chorionic villus sampling yielded an average of 14.8 mg villi (±2.7 SD; range, 5 to 30 mg) for cytogenetic analysis. We sought to mimic this amount in obtaining tissue for cytogenetic analysis from second-trimester pregnancy terminations; an average of 17.8 mg villi (±1.3 SD; range 15 to 20 mg) was actually obtained from these specimens. Forty-nine patients were in the second trimester (14 to 24 weeks' gestation) and eight were in the third trimester (25 to 37 weeks) at the time of chorionic villi collection.

Direct analysis of cytotrophoblastic cells yielded metaphases suitable for cytogenetic analysis in 56 of 57 (98.2%) cases. At least eight metaphases were analyzed from each direct preparation. In all cases results were available within 3 days (mean, 1.8 days ± 0.53 SD; range, 0.5 to 3 days). In the only three cases in which results were requested in <24 hours, rapid diagnosis was achieved. Of the 56 cases in which metaphases were obtained, 48 (85.7%) revealed normal complements (46,XY or 46,XX) and eight (14.3%) revealed abnormal complements (three cases of trisomy 21 and one case each of trisomy 18, 45,X, 46,XY,−22,+der(9), 47,XXY, and 69,XXX, respectively). The sole direct failure occurred in a 5 mg chorionic villus specimen obtained by transabdominal chorionic villus sampling at 19 weeks and incubated for 15 hours; cytogenetic results (46,XY) were later obtained by analysis of cultured mesenchymal core cells.

For confirmation of results obtained by direct analysis, cultured mesenchymal core cells were used to obtain metaphases in the 57 cases. Results were available within 17 days (mean, 10.8 days ± 3.8 SD; range, 6 to 17 days). In addition, fetal tissue (fibroblasts) for cytogenetic analysis was obtained from all pregnancy termination cases and yielded suitable metaphases in all 47 cases. Results obtained from direct analyses were corroborated in all cases.

Comment

Cytogenetic analysis of chorionic villi from second- and third-trimester placentas is known to be a reliable method for obtaining fetal cytogenetic information.[1-7] Direct analysis of first-trimester chorionic villi (cytotrophoblastic cells) provides a more rapid method for obtaining cytogenetic results,[8, 9, 12] and offers potential clinical advantages in the second and third trimesters. Although so-called direct analysis of chorionic villi has been reported in second- and third-trimester chorionic villus specimens, much variation exists in the definition of "direct analysis." Not all techniques actually produce results as rapidly as their name implies. Results are sometimes not available until at least 3 to 4 days, an interval that offers no advantage over that in routine culture of lymphocytes obtained by percutaneous umbilical blood sampling. For example, Hogdall et al.[5] used a "48 hour short-term incubation period" before cell fixation. By contrast, at our institution we restrict the term "direct analysis" to cytogenetic evaluation of

separated cytotrophoblastic cells that are incubated for only a short (3 to 15 hours) time period before cell fixation. The mean time from procedure to preliminary results is 1.8 days, compared with 10.8 days for analyses of cultured villi. In this study, chorionic villus samples were obtained from 49 placentas ≤24 weeks' gestation and eight placentas >24 weeks' gestation; direct preparations from all third-trimester cases provided adequate metaphase spreads for cytogenetic analysis. Furthermore, in those three instances in which rapid diagnosis was required for diagnostic purposes, results were available within 24 hours. Our findings are thus comparable with those of Holzgreve et al.[3] and Basaran et al.[4] who followed the technique of Simoni et al.,[13] who used a 1.25-hour incubation period before cell fixation and usually obtained cytogenetic results within 48 hours.

Evaluation of fetal cytogenetic complement in the second and third trimester is not infrequently necessary, and sometimes direct analysis of uncultured cytotrophoblastic cells is the only method to provide critical information. In the second trimester cytogenetic analysis is useful for those patients who are seen so late in gestation that amniocentesis could not provide information with regard to fetal status in sufficient time to allow pregnancy termination. In the third trimester cytogenetic analysis is as applicable as percutaneous umbilical blood sampling for patients at increased risk for fetal chromosome abnormalities. Indications include nonlethal malformations detected by ultrasonography or unexplained intrauterine growth retardation. Transabdominal chorionic villus sampling is the only plausible alternative if percutaneous umbilical blood sampling is not technically possible (e.g., oligohydramnios). Moreover, conventional analysis of lymphocytes obtained from percutaneous umbilical blood sampling usually requires a longer time (48 to 72 hours) to obtain results than is required by direct analysis of cytotrophoblastic cells (12 hours, if necessary).[13] Of note, however, is our previous description of a technique in which spontaneously dividing cells in fetal blood can be used to obtain cytogenetic results within 24 hours.[10, 14]

Although initial results are promising, the safety and accuracy of second- and third-trimester transabdominal chorionic villus sampling remain to be assessed fully. Initial reports indicate that transabdominal chorionic villus sampling in the first and second trimesters is a relatively safe procedure[5-7]; however, the safety of transabdominal chorionic villus sampling in the second and third trimesters has yet to be addressed. Our own direct preparations were all confirmed by analyses of cultured mesenchymal core cells or cultured fetal tissue, but additional data are still necessary to fully evaluate the diagnostic accuracy of cytogenetic analysis of cytotrophoblastic cells obtained from second- and third-trimester placentas. Discrepancies between cytogenetic analysis of cytotrophoblastic cells and mesenchymal core cells obtained from first-trimester placentas are well documented,[8, 9, 12] and it would not be surprising if similar discrepancies existed later in pregnancy. Indeed reports from several centers[2, 15-17] indicate that diagnostic problems (e.g., placental mosaicism) encountered in cytogenetic analysis of chorionic villi from first-trimester placentas similarly have been encountered in cytogenetic analysis of second- and third-trimester chorionic villi.

Perinatal mortality in Victoria, Australia: Role of group B streptococcus

John R. Fliegner, MD,[a] and Suzanne M. Garland, MD[b]
Parkville and Carlton, Australia

Group B β-hemolytic streptococcus is the most common infective cause of neonatal morbidity and mortality. It is therefore surprising that no agreement exists for an approach to its prevention. There is also increasing evidence that occult infection may play an etiologic role in premature rupture of the membranes and preterm labor. In this report we review the role of group B β-hemolytic streptococcal sepsis as a cause of perinatal wastage in the state of Victoria, Australia during the period 1982 to 1987. Group B β-hemolytic streptococcus accounted for 1.7% of overall perinatal deaths, and for 30.3% (77 of 254) perinatal deaths directly attributable to infection. By comparison, over the same 6-year period, erythroblastosis accounted for 0.5% of perinatal wastage and there were only two deaths as a result of congenital syphilis. The true incidence of lethal group B β-hemolytic streptococcal infection is probably greater because of the absence of histologic and bacteriologic studies in many perinatal deaths. We believe that intrapartum chemoprophylaxis with penicillin of all group B β-hemolytic streptococcus-positive carrier mothers would significantly reduce neonatal morbidity and mortality from this cause. (Am J Obstet Gynecol 1990;163:1609-11.)

Key words: Group B β-hemolytic streptococcus, perinatal wastage

The group B streptococcus organism is the most common cause of severe prenatal infection in our institution. The clinical signs of early onset disease are nonspecific and occur in other conditions associated with prematurity. The most frequent manifestation includes sepsis with pneumonia, bacteremia without a focus, or with meningitis. In some infants septic shock with neutropenia dominates the clinical picture and in these cases infection can be extremely fulminating and has an associated high mortality. The pathogenesis of infection is vertical transmission from a mother with genital group B β-hemolytic streptococcus colonization, and acquisition to the infant occurs just before delivery (through ruptured or intact membranes) or during birth canal passage. Although a few women have chorioamnionitis, most are asymptomatic before delivery and fail to signal any risk of infant infection unless preterm delivery occurs. Hematogenous spread may be prevented or aborted by early antibiotic treatment intrapartum. Infants may be infected in utero; this may be manifested clinically as fetal distress, late decelerations on fetal monitoring, and low Apgar scores at birth, or intrauterine death may occur. We report the impact of group B streptococcal infection on perinatal deaths for the State of Victoria, Australia, for the 6-year period from 1982 to 1987.

Material and methods

One of the authors (J. F.) has been a member of the Consultative Council on Obstetric and Perinatal Mortality and Morbidity since 1973. Since 1962 this committee has reviewed all perinatal deaths in the state of Victoria on an annual basis. Victoria has a population of four million and an annual confinement rate of over

Table I. Perinatal mortality and role of infection as a cause in Victoria between 1982 and 1987

Year	*Total births (live births and still births)*	*Perinatal deaths (SB and NNDs)*	*Perinatal deaths caused by infections*	*Perinatal deaths caused by GBS infection*
1982	60,455	897	39 (4.4%)	10
1983	60,591	774	37 (4.8%)	7
1984	60,704	765	55 (7.2%)	20
1985	61,176	741	37 (5.0%)	10
1986	61,253	680	48 (7.1%)	17
1987	61,474	677	38 (5.6%)	13

SB, Stillbirth; *NND*, neonatal death; *GBS*, group β streptococcal.

60,000. The perinatal mortality and rate of infection for the study period were reviewed. Specific attention was paid to the role of group B β-hemolytic streptococcus sepsis as a cause of perinatal wastage.

Definitions of stillbirth and neonatal death as defined by the Victorian Council are as follows: stillbirth—a stillborn infant weighing ≥500 gm, or, if the weight is not known, born after at least 22 weeks' gestation; neonatal death—a death occurring within 28 days of birth in an infant whose birth weight was ≥500 gm or, if the weight is not known, an infant born after at least 22 weeks' gestation; perinatal mortality rate—the number of perinatal deaths (stillbirths plus neonatal deaths) per 1000 births (live births and stillbirths).

Results

The overall perinatal mortality, the role of infection, and perinatal deaths caused by group B β-hemolytic streptococcus are summarized in Table I. For the 6-year period (1982 to 1987) the occurrence of infection as the direct cause of perinatal death fluctuated between 4.4% and 7.2%. However, group B β-hemolytic streptococcus infections for the entire period have been the most common causative agent responsible. In 1984 there were 20 losses attributed to group B β-hemolytic streptococcus infection; this accounted for 2.5% of all perinatal deaths and 36.4% of all infection cases. By comparison, during this 6-year period there were 24 perinatal deaths as a direct result of *Escherichia coli* infection, and only two from syphilitic infection. During the same period erythroblastosis accounted for 23 (0.5%) of total perinatal deaths.

In our institution (Royal Women's Hospital, Carlton) during the 8-year period from 1981 to 1988 a total of 30,197 live births were analyzed in which prenatal group B β-hemolytic streptococcus screening at 32 weeks was performed. There were no cases of neonatal group B β-hemolytic streptococcus sepsis among infants of asymptomatic carrier women who received intrapartum penicillin prophylaxis. By contrast, there were 27 infections with nine deaths in a control group of 26,915 infants when maternal group B β-hemolytic streptococcus screening had not occurred.

Comment

We analyzed the importance of group B β-hemolytic streptococcus disease as a cause of perinatal wastage in Victoria, Australia, during the 6 years from 1982 to 1987. During this period group B β-hemolytic streptococcus infection was responsible for 77 of 254 perinatal deaths (30.3%) attributable to infection, and accounted for 1.7% of overall perinatal deaths.

There is increasing evidence that asymptomatic group B β-hemolytic streptococcus carriage may be followed by occult chorioamnionitis, premature rupture of membranes, and perinatal infection.[1] However, although the impact of early-onset group B β-hemolytic streptococcus sepsis on neonatal mortality and morbidity is well recognized, its role as a cause of unexplained stillbirth in late pregnancy is not. The pathologist may overlook the condition in the absence of inflammatory changes, or perinatal risk factors such as pyrexia, premature rupture of membranes, or premature labor. The diagnosis of fulminating group B β-hemolytic streptococcus sepsis is further complicated by the occurrence of maceration, delays in autopsy, and secondary bacterial contamination. It has been established that a major risk factor associated with the development of perinatal group B β-hemolytic streptococcus sepsis is the intensity of colonization of the lower genital tract at the onset of labor.[2] When maternal group B β-hemolytic streptococcus carriage rates are low, it is claimed that mass screening in pregnancy is unlikely to be cost effective.[3] Thus in the United Kingdom, with an overall rate of group B β-hemolytic streptococcus infections of 0.3 per 1000 live births, this would involve screening over 3000 women to detect one case of group B β-hemolytic streptococcus sepsis. The situation is different in the United States and Australia. In a recent U.S. report, the incidence of severe neonatal sepsis

caused by group B β-hemolytic streptococcus infection was 4.62 cases per 1000 births, with a neonatal mortality of 0.8 per 1000 live births.[4]

In conclusion, we think that potentially avoidable perinatal deaths (in addition to serious neonatal sepsis) will continue unless the question of maternal group B β-hemolytic streptococcus colonization is addressed. At the Royal Women's Hospital, Melbourne, Australia, we have established that intrapartum penicillin prophylaxis in women with positive group B β-hemolytic streptococcus cultures at 32 weeks' gestation can prevent early-onset group B β-hemolytic streptococcus sepsis. Such a procedure is simple, cost effective, and may have important medicolegal implications in the future.

We thank the Consultative Council on Obstetric and Paediatric Mortality and Morbidity in Victoria for permission to use data from the annual reports covering the years 1982 to 1987.

Longitudinal study of the renin-angiotensin-aldosterone system in hypertensive pregnant women: Deviations related to the development of superimposed preeclampsia

Phyllis August, MD, Tomas Lenz, MD, Kathy L. Ales, MD, Maurice L. Druzin, MD, Terri G. Edersheim, MD, J. Milton Hutson, MD, Franco B. Müller, MD, John H. Laragh, MD, and Jean E. Sealey, DSc

New York, New York

A prospective longitudinal study of 25 pregnant women (30 pregnancies) with chronic hypertension, a group prone to development of preeclampsia, was conducted to explore the relationship between the renin-angiotensin-aldosterone system and the development of superimposed preeclampsia. In women with chronic hypertension in whom preeclampsia did not develop (17 pregnancies), blood pressure decreased and the renin-angiotensin-aldosterone system was stimulated, beginning in the first trimester and continuing throughout pregnancy as found previously in normotensive pregnant women (n = 58). Plasma estradiol and progesterone levels also increased progressively. In women with chronic hypertension in whom preeclampsia developed (13 pregnancies), blood pressure decreased and the renin-angiotensin-aldosterone system was stimulated in the first trimester as in the other groups. However, later in pregnancy significant differences were observed. Blood pressure began to rise in the second trimester. Initially the renin-angiotensin-aldosterone system remained stimulated, but in the early third trimester, when preeclampsia was diagnosed, plasma renin activity and urine aldosterone excretion decreased, and atrial natriuretic factor increased. These data provide information that may be useful in the recognition of superimposed preeclampsia, and in the investigation of its pathogenesis. (AM J OBSTET GYNECOL 1990;163:1612-21.)

Key words: Chronic hypertension, preeclampsia, renin-angiotensin-aldosterone system

Preeclampsia is a common and serious disorder that occurs most often in primigravid women and women with chronic hypertension. Women in whom preeclampsia develops in the latter half of pregnancy are not easily identified early in pregnancy, and therefore there is little information on hormonal or hemodynamic alterations before clinical disease is apparent. To overcome this limitation, we studied the renin-angiotensin-aldosterone system, plasma estradiol, and progesterone levels and renal function in each trimester of pregnancy in women with chronic hypertension. Such women have an increased incidence of superimposed preeclampsia (as high as 30%)[1]; therefore longitudinal studies of these women are more likely to yeild data on early pregnancy events that precede the clinical manifestations of preeclampsia. We report the results of a longitudinal investigation of the renin system, renal function, and pregnancy hormones in 30 pregnancies complicated by chronic hypertension and compare them with 58 normotensive pregnant women studied previously by us.[2,3] Our goal was to correlate these parameters with clinical events, and to identify alterations that might clarify our understanding of pregnancy hypertension.

Methods

Study population. Twenty-five women with chronic hypertension were followed up longitudinally during 30 pregnancies in the outpatient offices of the Department of Obstetrics and Gynecology and the Cardiovascular Center of The New York Hospital–Cornell Medical Center. The women were seen every 2 to 4 weeks throughout pregnancy. At each visit, blood pressure measurements were obtained on three occasions with a mercury sphygmomanometer with the patient in the seated position. The fifth Korotkoff signal was recorded for diastolic blood pressure. Antihypertensive medications were adjusted to maintain blood pressure ≤150/100 mm Hg.

Chronic hypertension was defined as a blood pressure level before pregnancy or in the first trimester of >140/90 mm Hg on at least two occasions. Superim-

posed preeclampsia in women with preexisting chronic hypertension was defined as a rise in blood pressure of 30/15 mm Hg in association with either significant proteinuria (≥2+ or ≥300 mg/24 hours) or thrombocytopenia and abnormal liver function tests.[4] Patients were hospitalized when superimposed preeclampsia was either suspected or diagnosed.

The control group consisted of 58 normotensive pregnant women who were seen at least once during the first and second trimester, and two to three times (at 30, 35, and 40 weeks) during the third trimester. The selection and clinical follow-up of 44 of these normotensive women and the laboratory data of 14 of the 58 women have been previously described.[2, 3] The clinical and laboratory data of the remaining women have not been previously reported.

Infant birth weight was recorded in the delivery room. Infants were classified as small for gestational age if their birth weights were <10th percentile for a given gestational age.[5]

Laboratory studies. Venous blood and 24-hour urine collections were obtained in the first trimester, second trimester, and in the early, middle, and late third trimester when possible. Blood was drawn with patients in the seated position after they had been ambulatory.

Blood for plasma renin activity was drawn into tripotassium ethylenediamine tetraacetic acid Vacutainer blood collection tubes (Becton-Dickinson, Rutherford, N.J.) and processed at room temperature to avoid cryoactivation of prorenin.[6, 7] Samples were stored at −40° C and thawed only once before assay for plasma renin activity. Plasma renin activity was measured by radioimmunoassay of the angiotensin I generated during incubation for 3 or 18 hours at 37° C and pH 5.7 in the presence of converting enzyme and angiotensinase inhibitors, using endogenous angiotensinogen as the source of renin substrate. Results are expressed as nanograms of angiotensin I per milliliter per hour. Plasma total renin was measured as described for plasma renin activity after conversion of prorenin to renin with solid-phase trypsin.[8] Plasma prorenin was calculated by subtracting plasma renin activity from total renin. Plasma prorenin V_{max} was also calculated from the prorenin and angiotensinogen levels by use of the Michaelis—Menten equation as previously described.[9] Plasma angiotensinogen was measured as the amount of angiotensin I formed after incubation with excess human renin (6.6×10^{-2} Goldblatt units/ml).[6] The coefficient of variation of plasma renin activity and angiotensinogen is 7.6% and that of prorenin is 9.4%.

Blood for atrial natriuretic factor was drawn into chilled tripotassium ethylenediamine tetraacetic acid Vacutainer blood collection tubes and kept on ice. Samples were extracted on C18 Sep-Pak cartridges (Waters, Milford, Mass.) and radioimmunoassay was performed as previously described.[10]

Urine aldosterone was measured with a Coat-a-Count aldosterone kit (Diagnostic Products, Los Angeles). The assay was validated for use in pregnancy by showing that separation of aldosterone from other steroids by chromatography[11] did not reduce the reported values. In addition, we found that exogenous estradiol, progesterone, and human chorionic gonadotropin did not offset the radioimmunoassay. Plasma estradiol and progesterone concentrations were measured with commercially available radioimmunoassay kits (Serono Laboratories, Braintree, Mass.).

Plasma renin and urinary aldosterone were assayed as the samples were collected because these results were often used for clinical purposes. Plasma renin activity was always assayed within 2 days of collection. For the other hormones the samples for a particular patient were usually run in the same set.

Serum creatinine was assayed by multichannel automated techniques. Urinary creatinine levels were determined by an Autoanalyzer (Technicon, Tarrytown, N.Y.), and urinary sodium levels were determined by flame photometry. Urinary protein was measured by nephelometry after precipitation with trichloroacetic acid.[12]

Statistical analysis. One-way analysis of variance was used for statistical analysis of data. Blood pressure, hormones, renal parameters were compared between groups at each time period. In each group, comparisons (analysis of variance) were made between different weeks of gestation. Adjustments for multiple comparison were made with the method of Bonferroni. Tests of normality of data were performed by determining the ratio of skewness to its standard error, and the ratio of kurtosis to its standard error. For nonparametrically distributed data the Kruskal-Wallis one-way analysis of variance was used.[13]

Results

The clinical features of the 88 pregnancies are summarized in Table I.

Maternal clinical characteristics. Thirteen of the 30 hypertensive pregnancies (43%) were complicated by superimposed preeclampsia. In one woman this complication developed at 23 weeks, and in others in the third trimester. As expected, the women with superimposed preeclampsia had earlier deliveries (Table I).

Of the 13 pregnancies with superimposed preeclampsia, nine women had essential hypertension, two women had systemic lupus erythematosus (three pregnancies), and one woman had renovascular hypertension. One woman with systemic lupus erythematosus received prednisone during her entire two pregnancies to control thrombocytopenia. Two women were treated with low-dose aspirin because of high titers of anticardiolipin antibodies. Antihypertensive medications are discussed.

Table I. Description of study subjects

	Normal (n = 58)	*Chronic hypertension (n = 17)*	*Chronic hypertension with superimposed preeclampsia (n = 13)*
Maternal age (yr)	31 ± 1	32 ± 1	32 ± 1
No. of primigravid women	11/58	6/17	5/13
Gestational age at delivery (wk)	38 ± 0.4	38 ± 0.6	32 ± 1.2*
Birth weight (gm)	3430 ± 4	2616 ± 5‡	1721 ± 8†
Small for gestational age	1/58	1/17	2/13
Perinatal mortality (%)	2	0	15

Data are presented as mean ± SEM.
*$p < 0.005$, compared with normal subjects and pregnancies complicated by chronic hypertension.
†$p < 0.001$, compared with normal subjects and pregnancies complicated by chronic hypertension.
‡$p < 0.005$, compared with normal subjects.

Seventeen pregnancies in women with chronic hypertension were not complicated by preeclampsia. In 15 of these 17 women the diagnosis was essential hypertension. One women had renovascular hypertension, and one had renal hypertension (unilateral renal scar).

Infant outcome. The women with superimposed preeclampsia were delivered earlier, and their infants, as expected were smaller compared with infants of normotensive mothers and women with uncomplicated chronic hypertension ($p < 0.001$) (Table I). The infants born to mothers with uncomplicated chronic hypertension were also smaller compared with normal women ($p < 0.005$) (Table I), even though the average gestational age was the same. There were two small-for-gestational-age infants born to mothers with superimposed preeclampsia (15%). There was one intrauterine death (6%) and one perinatal death (6%) in the group with superimposed preeclampsia. Therefore the incidence of serious fetal morbidity and mortality in this group was almost 30%. There was one perinatal death caused by a cord accident and one small-for-gestational-age infant in the normotensive women. There were no perinatal deaths and only one small-for-gestational-age infant in the pregnancies of women with uncomplicated chronic hypertension.

Blood pressure. The sequential changes in systolic and diastolic blood pressure in women with chronic hypertension and normotensive women are illustrated in Fig. 1. It is evident that the blood pressure during pregnancy was higher ($p < 0.001$) in cases of chronic hypertension. It is also evident that the blood pressure decreased significantly ($p < 0.01$) during the first trimester in all hypertensive women, even in those with superimposed preeclampsia. However, in cases of uncomplicated chronic hypertension and normotension, blood pressure continued to decrease in the second trimester, reached a nadir at 28 weeks, and then rose to early pregnancy or prepregnancy levels. In contrast, blood pressure did not decrease after 10 weeks in the women in whom preeclampsia developed but remained constant or increased until the third trimester when preeclampsia was diagnosed (Fig. 1).

Renal function. Creatinine clearances (mean ± SEM) in early pregnancy were similar in normotensive women (126 ± 7 ml/min), women with uncomplicated chronic hypertension (108 ± 9 ml/min), and women with chronic hypertension in whom superimposed preeclampsia developed (129 ± 10 ml/min). Two women with chronic hypertension had proteinuria (>300 mg but <1 gm/24 hours) before and during pregnancy. The other patients had protein excretion <300 mg/24 hours.

Creatinine clearance decreased slightly only in the women in whom preeclampsia developed (129 ± 22 ml/min in the first trimester to 97 ± 13 ml/min in the third trimester, p = NS). Significant proteinuria (>300 mg/24 hours) developed in 10 of 13 women with superimposed preeclampsia in the third trimester. In the remaining three women, superimposed preeclampsia was diagnosed on the basis of a rise in blood pressure, hyperuricemia, abnormal liver function tests, and thrombocytopenia.

Renin-angiotensin-aldosterone system

Plasma renin activity. Sequential determination of plasma renin activity revealed several differences among normotensive women, women with uncomplicated chronic hypertension, and women with chronic hypertension with superimposed preeclampsia. Plasma renin activity peaked earlier in women with chronic hypertension in whom superimposed preeclampsia developed as a group and clearly later (at 32 weeks) in normotensive women and women with chronic hypertension (Fig. 2, *A*). Moreover, plasma renin activity de-

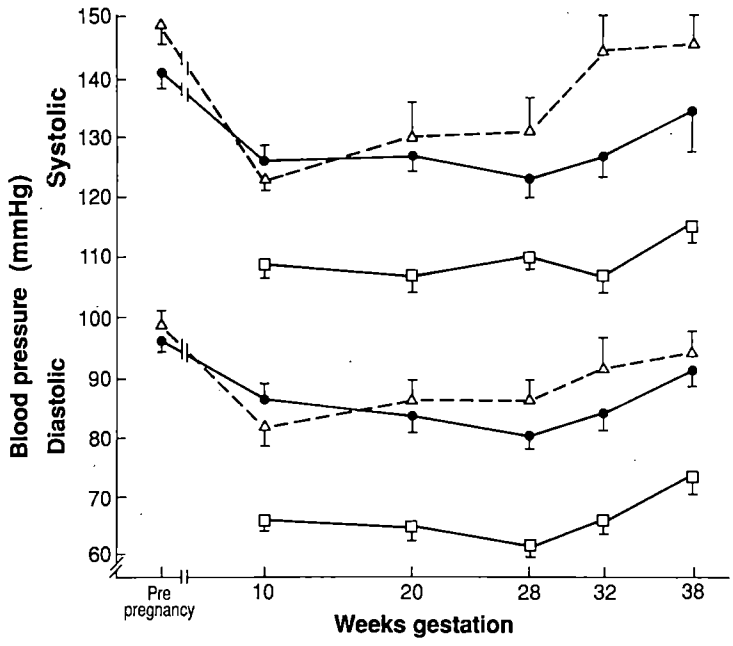

Fig. 1. Serial changes in systolic and diastolic blood pressure throughout pregnancy in normotensive women (n = 14, □——□), women with uncomplicated chronic hypertension (n = 17, ●——●), and women with chronic hypertension with superimposed preeclampsia (n = 13, △ - - - △) (mean ± SE).

creased significantly from 20 to 32 weeks in women with chronic hypertension and superimposed preeclampsia ($p < 0.01$) and increased significantly in normotensive pregnancies ($p < 0.01$). This differential profile resulted in a significantly lower plasma renin activity in women with preeclampsia compared with normotensive women at 32 weeks and not at 20 weeks. In women with uncomplicated chronic hypertension plasma renin activity remained almost constant from 20 weeks until term (Fig. 2, *A*). Late third-trimester plasma renin activity correlated with infant birth weight in the 88 pregnancies reported here ($r = 0.39$, $p < 0.01$), in accord with earlier observations made by our group.[14]

Plasma renin activity was similar in all three groups with respect to an increase in early pregnancy and a decrease in the postpartum period.

The data were reanalyzed to include only patients with essential hypertension and exclude those with renovascular hypertension, renal hypertension, or systemic lupus erythematosus, because the renin-angiotensin system might behave differently in these conditions. In these 24 pregnancies (15 with uncomplicated essential hypertension, nine with superimposed preeclampsia), the patterns of plasma renin activity were identical to those described above for the larger group. Plasma renin activity rose early in pregnancy and remained elevated until term in the women with uncomplicated essential hypertension. In contrast, in the women in whom superimposed preeclampsia developed, plasma renin activity rose early in pregnancy and then decreased after 20 weeks. Plasma renin activity in these women was significantly lower in the third trimester compared with the normotensive women and those with uncomplicated essential hypertension.

Urine aldosterone. In a fashion similar to plasma renin activity, urine aldosterone excretion differed in women with chronic hypertension with superimposed preeclampsia compared with those with chronic hypertension or normotensive women. As illustrated in Fig. 2, *B*, urine aldosterone excretion peaked earlier in women with preeclampsia. Furthermore, at 32 weeks, urine aldosterone was significantly lower in women with preeclampsia compared with normotensive women and women with uncomplicated chronic hypertension (Fig. 2, *B*). These patterns were maintained when only women with essential hypertension were analyzed (n = 24 pregnancies).

Plasma renin activity correlated with urine aldosterone in normotensive women ($r = 0.52$, $p < 0.001$). In hypertensive women the correlation between plasma renin activity and urine aldosterone was not strong ($r = 0.23$, $p = 0.05$ in uncomplicated chronic hypertension, and $r = 0.48$, $p = 0.05$ in women with preeclampsia).

Sodium excretion over 24 hours was similar in all three groups during pregnancy, except in the first trimester in the women with chronic hypertension with superimposed preeclampsia, in whom it was higher.

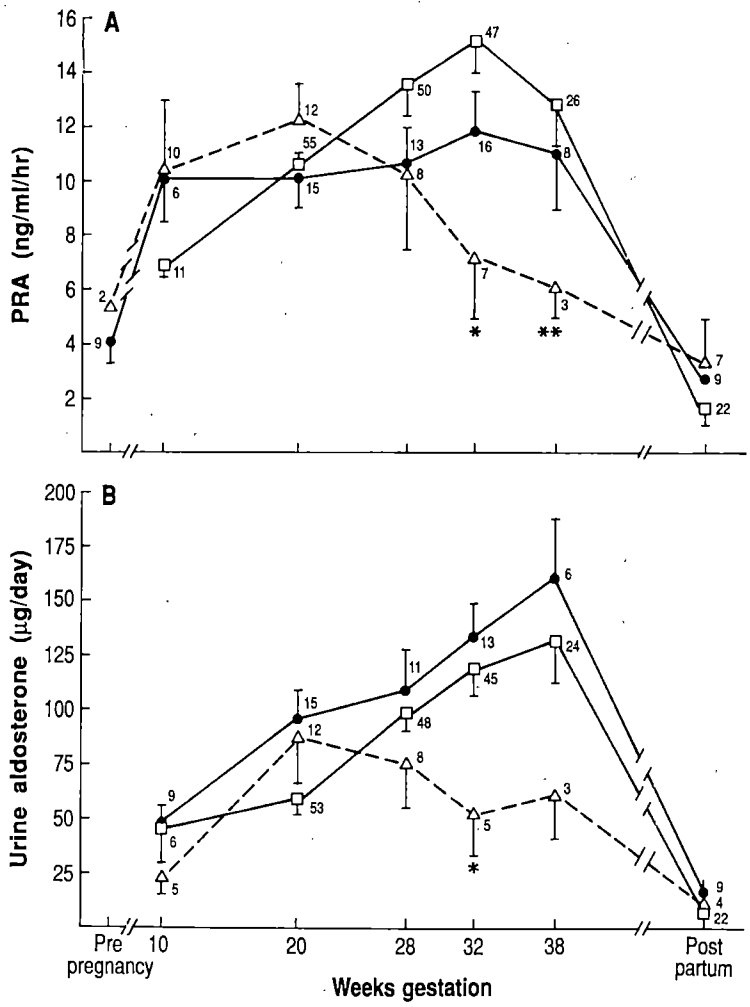

Fig. 2. Serial changes in plasma renin activity *(PRA)* **(A)** and urine aldosterone excretion **(B)** before, during, and after pregnancy in normotensive women (□——□), women with uncomplicated chronic hypertension (●——●), and women with chronic hypertension with superimposed preeclampsia (△ - - - △) (mean ± SE). *Numbers in parentheses* refer to the number of patients analyzed at each time point. Data were obtained within 2 weeks of each time point indicated on the X axis. **A,** First-trimester plasma renin activity rose significantly ($p < 0.005$) in women with uncomplicated chronic hypertension. Post partum, plasma renin activity was significantly lower than first- and second-trimester plasma renin activity in all groups. In women with superimposed preeclampsia, plasma renin activity at 32 and 38 weeks was significantly lower (*asterisk*, $p < 0.05$, *double asterisks*, $p < 0.01$) compared with the 20-week value. Plasma renin activity at 32 weeks was significantly lower ($p < 0.05$) than plasma renin activity at similar gestational age in normotensive women. **B,** Urine aldosterone was significantly lower post partum than during pregnancy in all groups. In women with superimposed preeclampsia urine aldosterone was lower ($p < 0.05$) at 32 weeks compared with urine aldosterone in normotensive women and women with uncomplicated chronic hypertension at similar gestational age.

The renin-aldosterone profile clearly distinguished, not only as a group but also in individual instances, the women with chronic hypertension with preeclampsia from those with chronic hypertension without superimposed preeclampsia. Figs. 3 and 4 show data from individual women that demonstrates the different features of the renin-aldosterone profile in women with chronic hypertension with superimposed preeclampsia compared with those with uncomplicated chronic hypertension.

Effect of antihypertensive therapy on plasma renin activity. A potential cause for lower plasma renin activity in women with chronic hypertension and superimposed preeclampsia could be treatment with drugs

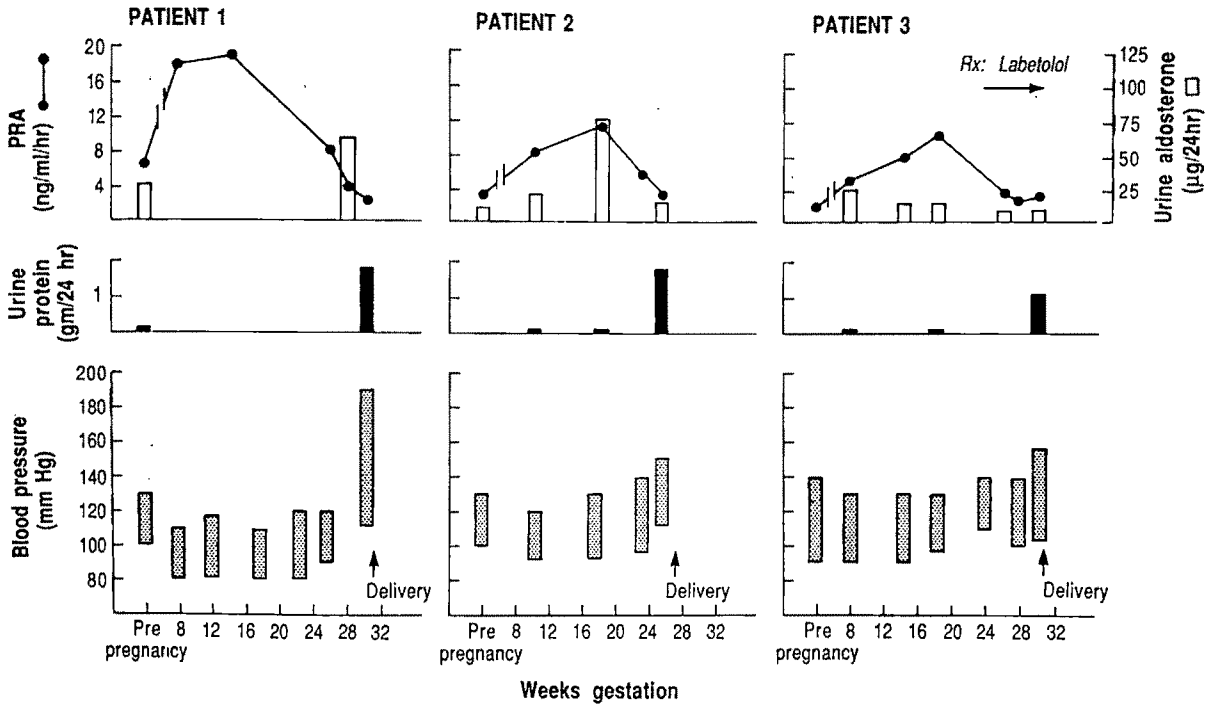

Fig. 3. Serial changes throughout pregnancy in plasma renin activity *(PRA) (solid line)*, urine aldosterone *(open bars)*, urine protein *(solid bars)*, and systolic and diastolic blood pressure in three women with chronic hypertension in whom superimposed preeclampsia developed. Patient 1 had a growth-retarded infant and patient 2 had an intrauterine death. Patient 3 was treated with labetalol during the third trimester.

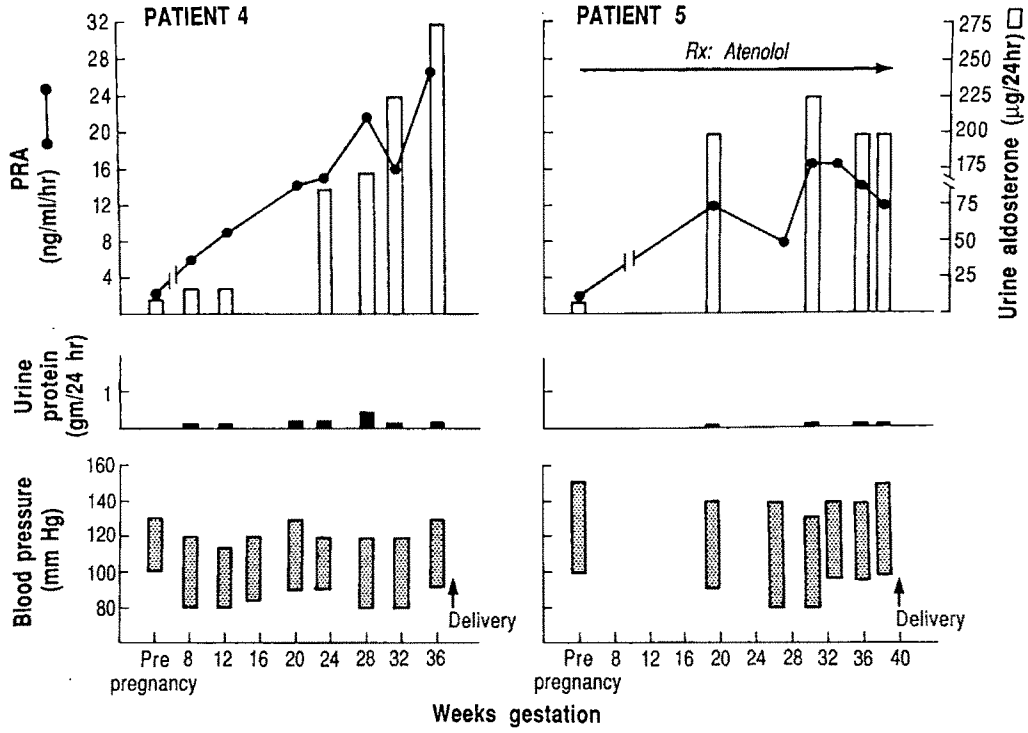

Fig. 4. Serial changes throughout pregnancy in plasma renin activity *(PRA) (solid line)*, urine aldosterone *(open bars)*, urine protein *(solid bars)*, and systolic and diastolic blood pressure in two women with uncomplicated chronic hypertension. Patient 4 received aspirin 80 mg/day, beginning at 12 weeks and continuing until term. Patient 5 was treated with atenolol during the entire pregnancy.

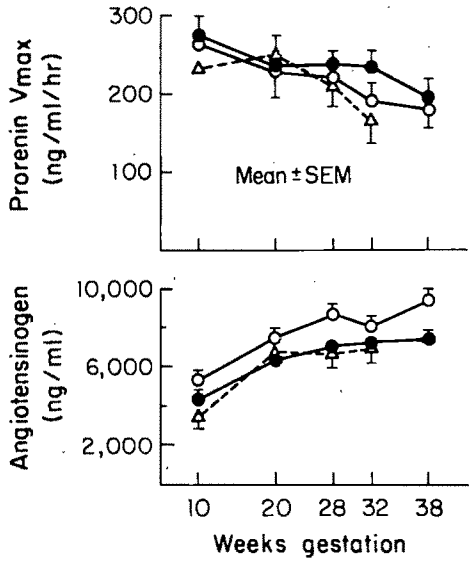

Fig. 5. Serial changes in prorenin V_{max} and angiotensinogen during pregnancy in normotensive women (○——○, $n = 58$), women with uncomplicated chronic hypertension (●——●, $n = 17$), and women with chronic hypertension with superimposed preeclampsia (△ - - - △, $n = 13$).

that affect plasma renin activity, for example, β-blockers. Of the 17 women with uncomplicated chronic hypertension, eight received antihypertensive medication, and five of eight were treated with β-blockers before the 20-week blood specimens were collected. Although medication may have resulted in lower plasma renin activity at 20 weeks in these women, by 35 weeks plasma renin activity had risen in all eight cases despite treatment.

Of the 13 women with chronic hypertension and superimposed preeclampsia, seven received antihypertensive medication. In five of these pregnancies medications were begun before the second-trimester blood sampling. Because the significant decrease in plasma renin activity occurred between the second and third trimester, it is unlikely that antihypertensive medication was responsible for the decrease in third-trimester plasma renin activity. However, it is possible that therapy may have altered the third-trimester plasma renin activity in the three women in whom treatment (one with labetalol, two with methyldopa) was begun in the second trimester. In this context, it is noteworthy that plasma renin activity rose despite therapy with labetalol and methyldopa in women with uncomplicated chronic hypertension.

Plasma prorenin, angiotensinogen. Plasma prorenin and angiotensinogen (renin substrate) levels were similar in all three groups at all times during pregnancy (Fig. 5). The prorenin level was highest early in pregnancy, and decreased slightly toward term in all three groups as previously reported in normotensive women.[7] Angiotensinogen levels increased to a similar degree in all three groups during pregnancy (Fig. 5).

Estradiol and progesterone. In normotensive women and in women with uncomplicated chronic hypertension, plasma estradiol and progesterone levels increased steadily until term (Fig. 6). Serial measurements of estradiol and progesterone were made in six of 13 women in whom superimposed preeclampsia developed (Fig. 6, *B* and *D*). The progesterone level rose in four of these women as in the other groups. In two women there was no increase after the second trimester (Fig. 6, *B*).

Estradiol levels rose throughout pregnancy in two of six women with preeclampsia. In the other four cases the levels were abnormally low in both second and third trimesters (Fig. 6, *D*).

Atrial natriuretic factor. We measured atrial natriuretic factor longitudinally in 14 women with chronic hypertension, four of whom had superimposed preeclampsia. Atrial natriuretic factor levels in six of these women have been reported previously.[15] Atrial natriuretic factor levels in the women with uncomplicated chronic hypertension ($n = 10$) remained constant throughout pregnancy and were similar to atrial natriuretic factor levels previously reported for normotensive pregnant women and nonpregnant controls.[15] In three of the four women with preeclampsia, atrial natriuretic factor rose markedly in the third trimester in association with a decrease in plasma renin activity. The third-trimester atrial natriuretic factor (mean ± SE) level in the women with preeclampsia was higher compared with the cases of uncomplicated chronic hypertension and normotensive women (67.7 ± 9 vs 16.7 ± 3.2 and 15.6 ± 1.8 fmol/ml, $p < 0.02$).

Comment

The characterization of the renin-angiotensin-aldosterone system in hypertensive pregnancy has been difficult because of the lack of longitudinal data in the same patients. Earlier cross-sectional studies, although informative, are difficult to interpret because of the wide range of normal values for plasma renin activity in pregnancy. Even in studies in which plasma renin activity was measured serially during normal and hypertensive pregnancy,[16-18] components of the renin-angiotensin-aldosterone system have not been correlated with the development of preeclampsia, or with infant outcome.

To our knowledge, this is the first report of sequential data on the renin-angiotensin-aldosterone system, atrial natriuretic factor, pregnancy hormones, and renal function in a group of high-risk pregnancies com-

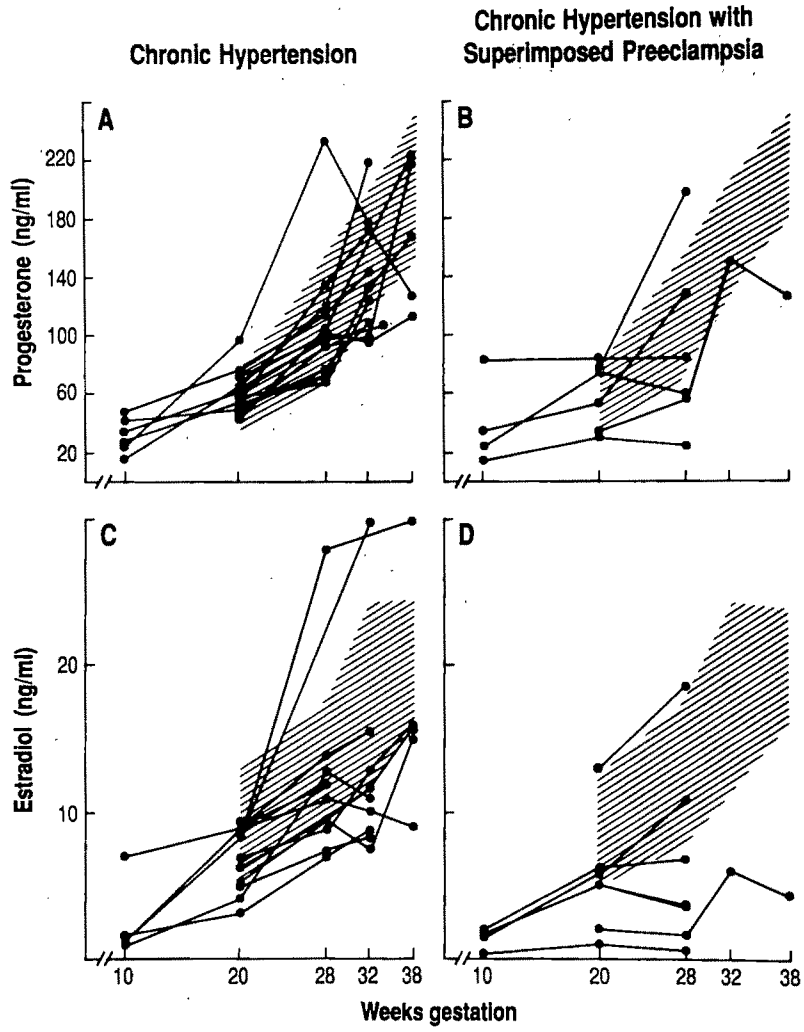

Fig. 6. Serial changes in plasma progesterone (**A** and **B**) and estradiol (**C** and **D**) in individual women with uncomplicated chronic hypertension (**A** and **C**) and those with chronic hypertension with superimposed preeclampsia (**B** and **D**). Data were obtained within 2 weeks of each time point indicated on the X axis. The *shaded area* represents the values (mean ± SD) obtained in normotensive women (n = 44).

plicated by chronic hypertension, many of which (43%) were further complicated by the development of preeclampsia. Hormonal data in 14 of the 58 normotensive controls has been previously published. A major finding of this investigation is that plasma renin activity and urine aldosterone levels decreased from previously normal (for pregnancy) levels in women with chronic hypertension as preeclampsia developed. These decreases were associated with a failure of estradiol to rise normally in the third trimester and perhaps an increase in circulating atrial natriuretic factor. Our study also demonstrates that in uncomplicated chronic hypertensive pregnancies, plasma renin activity and urine aldosterone excretion remained elevated throughout gestation, and estradiol and progesterone levels increased steadily until term in a fashion analogous to normotensive pregnancies.

Our finding of increased atrial natriuretic factor and suppressed plasma renin activity in women with preeclampsia suggests that the effective plasma volume may be expanded in this disorder. However, this notion disagrees with the observation that plasma volume (measured by Evans blue dye dilution), is lower in preeclampsia compared with normal pregnancy.[19] A possible explanation for this apparent inconsistency is that the measured decrease in plasma volume in preeclampsia does not truly reflect hypovolemia or underfilling, but rather the increased vasoconstriction has contracted the space to be filled. Alternatively, plasma atrial natriuretic factor may be increased in preeclampsia by mechanisms other than volume expansion, but still may inhibit renin directly.[20] Others have questioned the prevalent view that preeclampsia is characterized by decreased plasma volume and vasoconstriction.[21] It ap-

pears from our data that further studies may be warranted to resolve these issues.

It is most likely that the changes in plasma renin activity documented in this study are reflective of maternal renal renin secretion rather than placental renin because plasma renin activity in pregnant women responds appropriately to changes in sodium homeostasis.[22, 23] It has also been shown that increased vasodilatation during pregnancy results in stimulation of plasma renin activity.[24] Because progesterone is natriuretic,[25, 26] and there is evidence that estradiol mediates vasodilation,[27] it is possible that plasma levels of these hormones influence the renin-angiotensin-aldosterone system. Indeed, in this study, the stimulation of the renin-angiotensin-aldosterone system paralleled the rise in sex steroids, particularly in the normotensive women and women with uncomplicated chronic hypertension. Additional factors not measured in this investigation, such as vasodilatory prostaglandins, may also contribute to alterations in plasma renin activity in pregnancy.

The incidence of superimposed preeclampsia in our patients was unusually high compared with the previously reported incidence. Six of the women (20%) in our study had secondary hypertension, which may have been partially responsible for the high incidence. In addition, many of our patients were referred to our tertiary center because of previous pregnancies complicated by severe preeclampsia and fetal death. Nevertheless, this bias in our population has enabled us to investigate a small number of patients with a high percentage of cases of superimposed preeclampsia. Although it may be argued that there is a high degree of error in making a diagnosis of superimposed preeclampsia, we strictly applied the American College of Obstetricians and Gynecologists criteria[4] in classifying our patients with superimposed preeclampsia.

It may also be argued that the pathophysiologic features of preeclampsia, which is a disease of first pregnancy, may not be similar to "superimposed preeclampsia," which occurs in women who may be multiparous and who already have chronic hypertension. Therefore our findings may not be applicable to the classic primigravid woman with preeclampsia. However, it is well documented that most of the maternal and perinatal morbidity and mortality attributable to hypertensive pregnancy occurs in women with preexisting chronic hypertension in whom superimposed preeclampsia develops,[28] an observation that is supported by the data from our study and underscores the need to study such women.

In conclusion, we have demonstrated a decrease in plasma renin and urine aldosterone excretion in association with the development of superimposed preeclampsia and poor infant outcome. Although the basis for these alterations are not completely understood, our data suggest that (1) the renin-angiotensin-aldosterone system in both normotensive and hypertensive pregnancy responds to physiologic signals (e.g., changes in blood pressure, volume status) as in nonpregnant individuals and (2) alterations in placental hormones (e.g., estradiol, progesterone) and atrial natriuretic factor may be in part responsible for the alterations in the renin system in pregnancy. The possibility that inadequate suppression of the renin-angiotensin-aldosterone system may contribute to the elevation in blood pressure in preeclampsia has not been completely excluded in our study. Further studies of blocking of the renin-angiotensin-aldosterone system in hypertensive pregnancy are necessary to resolve this issue.

We thank Dr. M. Suthanthiran for his review of the manuscript.

A comparison of sperm antibody assays

Josef Daru, MD,* and Subbi Mathur, PhD**
Charleston, South Carolina

Cytotoxicity and Immunobead-binding immunoglobulin G assays agreed in 81% of sera from infertile men (n = 173), 74% of sera from their wives, 75% of seminal plasma, and 82% of cervical mucous samples ($p < 0.001$; χ^2 analysis of positive and negative results) when tested against sperm from the same donors. Cytotoxic and immunofluorescent IgG antibody results agreed in 79% of sera from men and women, 76% of seminal plasma, and 76% of cervical mucus ($p < 0.001$; χ^2 analysis of positive and negative results). Titers or percent binding of sperm by cytotoxicity, hemagglutination, and IgG Immunobead-binding or immunofluorescence assays in serum and secretions of husbands and wives correlated ($p < 0.001$). A significantly increased number of positive results was observed in cytotoxic and Immunobead-binding IgG assays when the husbands' and donors' sperm were used rather than donors' sperm alone. On the basis of this study we conclude: (1) that cytotoxicity, Immunobead-binding IgG, and immunofluorescent IgG sperm antibody assays correlate when sperm from the same source are used, (2) that women's isoimmunity to husbands' sperm is associated with their husbands' autoimmunity to sperm irrespective of the assay, and (3) that it is desirable to use sperm from the husbands and nonautoimmune fertile men in these assays. (Am J Obstet Gynecol 1990;163:1622-9.)

Key words: Sperm antibodies, sperm antigens, sperm cytotoxicity, sperm immobilization

Differences in basic principles of assays are the major limitations for blind studies that attempt to correlate results obtained by various sperm antibody assays and laboratories performing the same assay.[1, 2] For example, sperm agglutination assays identifying IgG2, IgG4, IgA or IgM may not wholly agree with sperm-immobilizing or cytotoxic antibody assays detecting IgG1, IgG3, and IgM in the presence of complement. It is inappropriate to compare assays that use whole semen with those using live swim-up spermatozoa free of seminal plasma.[1] The positive titers vary from laboratory to laboratory. Sperm from the same donors should be used when data from different sperm antibody assays are compared because results may vary as a result of the antigenic heterogeneity of sperm.[3, 4] Wives of autoimmune infertile men develop antibodies specifically against husbands' sperm antigens.[1, 5-9] This is attributed to special antigens present on the sperm of autoimmune infertile men.[10] It would seem appropriate to test the serum and secretions from both partners against sperm from husbands and fertile donors.

The goals of this study were as follows: (1) to compare cytotoxicity, hemagglutination, Immunobead-binding, and immunofluorescence assays using sperm from the same donor for each run, (2) verify the incidence of sperm antibodies in both partners of infertile couples, and (3) to ascertain the need to use husbands' sperm in the assays.

Material and methods

Two hundred one infertile couples, aged 28 to 42 years and with poor postcoital test sperm motility, participated after giving informed consent. We performed double fluorochromasia cytotoxicity, Immunobead-binding, immunofluorescence, and passive hemagglutination assays in a blinded fashion. Husbands' sperm and donors' sperm were used as target cells in the cytotoxicity and hemagglutination assays of all couples and in the Immunobead-binding and immunofluorescence assays of 28 couples. Sperm from the same fertile control donors were used in each run of all assays for all study subjects.

In the cytotoxic sperm antibody assay, viable swim-up sperm labeled with diacetylfluorescein (Eastman Organic Chemicals, Rochester, N.Y.) were exposed to cytotoxic sperm antibodies in serum or secretions in the presence of complement. Counterlabeling with ethidium bromide identified the dead sperm. The end point was the dilution at which 50% of the sperm stained red. Complement, cell, negative and positive controls were regularly used for quality control. The background staining of killed sperm in the cell controls in the pres-

ence of complement alone was maintained at ≤15%. The previously established positive antibody titers were ≥32 in sera and seminal plasma and ≥80 in cervical mucus.[8] The assay yielded 0% and 6% false-positive results in fertile men and women, respectively, in a World Health Organization collaborative study.[1]

The direct and indirect Immunobead-binding assays[11, 12] were modified as follows. Sperm from fertile, type O, Rh-positive, sperm antibody–free donors were used to avoid interference by blood group antibodies; microtiter plates were used instead of test tubes (results were similar in both systems); a serum and seminal plasma dilution of 1:32 and a cervical mucus dilution of 1:40 were used instead of 1:8 used in many laboratories because dilutions ≤8 may give nonspecific and prozone reactions; Immunobead reagents were kept sterile.

A sperm pellet washed free of seminal plasma and suspended in sperm medium (Irvine Scientific, Santa Ana, Calif.) was used for the direct assay. Then 50 μl of this sperm suspension (10^6/ml) was mixed with 50 μl of 5 mg/ml Immunobeads coupled with antibodies to human IgG, IgA, or IgM (Bio-Rad Laboratories, Richmond, Calif.) and incubated for 5 to 10 minutes to detect sperm IgG, IgA, and IgM.

In the indirect Immunobead-binding assay, 50 μl of viable motile swim-up sperm (10^6/ml) from the semen of fertile donors or husbands of infertile couples was mixed with 50 μl of a 1:16 dilution of serum or seminal plasma or 1:20 dilution of cervical mucus (final dilutions of 1:32 and 1:40, respectively) in microtiter plates that were then covered and incubated for 60 minutes at 37° C. After centrifuging at 400 *g* for 15 minutes, the supernatant was aspirated, and the sperm button was resuspended in 100 μl of medium. Fifty microliters of the suspension containing 5 mg/ml Immunobeads coupled with antibodies to human IgG, IgA, or IgM was added. After a 5- to 10-minute incubation, the reaction was observed by phase-contrast microscopy at ×400. Negative and positive controls were maintained for each run. A sperm was scored positive if two or more beads were bound to its surface. Samples with ≥15% of sperm that showed Immunobead binding were classified as positive.[11, 12]

In the Immunofluorescent antibody assay, motile swim-up sperm in phosphate-buffered saline solution washed free of seminal plasma were dropped on microscopic slides and air dried for a few seconds. The serum and seminal plasma samples diluted with phosphate-buffered saline solution to 1:32 and the cervical mucus diluted to 1:80 were immediately added to sperm before the latter were killed by drying. The incubation of sperm with the test samples and secondary antibodies was done at 4° C. Fab_2 fragments of fluorescein-conjugated rabbit antihuman IgG, IgA, and IgM (Calbiochem Laboratories, Los Angeles) were used to avoid nonspecific binding and capping of antigens. The slides were examined under a fluorescent microscope. The reactions were scored as −, +, ++, or +++ depending on the intensity of fluorescence. Positive and negative serum and cell controls were maintained.[13]

In the passive hemagglutination assay, human O, Rh-positive red blood cells were coated with a sonicated sperm extract or seminal plasma from the husbands or O, Rh-positive control fertile men.[8] Serial dilutions of patient sera, seminal plasma, and cervical mucus were titrated against red cells coated with the sperm extract or seminal plasma. The test samples were positive if their antibody titers were greater than or equal to the mean + 2 SD of the fertile controls (serum and seminal plasma, ≥32; cervical mucus, ≥80).[8]

The χ^2 analyses were done to assess the similarity between sperm antibody assays in estimating the positivity or negativity of the same sample. Linear regression analysis of antibody titers conventionally expressed as $\log_2$ for cytotoxicity and hemagglutination assays and percent binding by Immunobead binding and by immunofluorescence assays was additionally performed. Only those *p* values that were significant after Bonferroni correction for multiple testing are reported.

Results

Infertile men. Sera from ≥90% of 132 men who were negative for circulating cytotoxic sperm antibodies were also negative by other assays. The positive and negative results obtained by all assays were compared by χ^2 analysis. The best agreements were between cytotoxicity and Immunobead-binding IgG in 140 of 173 (81%) serum samples ($p < 0.001$); between cytotoxicity and immunofluorescent IgG in 136 of 173 (79%) samples ($p < 0.001$); and between immunofluorescent IgG and Immunobead-binding IgG in 135 serum samples. Hemagglutinating, Immunobead-binding, and immunofluorescence assays generally yielded higher numbers of false-negative than false-positive results ($p < 0.001$; Table I).

Seventy percent or more of infertile men without cytotoxic sperm antibodies in the seminal plasma also had negative results by other assays. Results obtained by cytotoxicity and Immunobead-binding IgG were similar in 129 of 173 (75%) of seminal plasma samples, whereas cytotoxicity and immunofluorescent IgG agreed in 132 of 173 (76%) of seminal plasma samples ($p < 0.0001$). Results by cytotoxicity did not agree with those of Immunobead binding or immunofluorescent IgM. Of 30 seminal plasma samples with Immunobead-binding IgM, 25 also had Immunobead-binding IgG. Higher percentages of men had IgA and IgM sperm

‡$p < 0.005$.

antibodies in the seminal plasma than in the serum (Table I).

Infertile women. More false-negative results were obtained with hemagglutinating, Immunobead-binding, and immunofluorescence assays than with cytotoxicity assay. Ninety percent or more of infertile women without cytotoxic sperm antibodies in the serum or cervical mucus ($n = 110$) also had negative results by the other assays. Results obtained by cytotoxicity and Immunobead-binding IgG agreed in 128 of 173 (74%) of serum and in 142 of 173 (82%) cervical mucous samples ($p < 0.0001$). Results obtained by cytotoxicity and immunofluorescent IgG agreed in 137 of 173 (79%) serum samples and in 142 of 173 (82%) cervical mucous samples ($p < 0.001$). Fourteen percent of serum and cervical mucous samples had cytotoxic and Immunobead-binding IgM sperm antibodies, whereas 24% of serum and 30% of cervical mucous samples had cytotoxic and immunofluorescent IgM sperm antibodies (Table II).

Few women had hemagglutinating, Immunobead-binding IgA and IgM and immunofluorescent IgA and IgM sperm antibodies in serum and cervical mucus (Table II).

Correlations between sperm antibody titers or percent binding by various assays. Cytotoxic sperm antibody titers ($\log_2$) correlated with percentages of sperm bound by Immunobead-binding and immunofluorescent IgG ($p < 0.001$ by linear regression analysis) in all study samples from both partners. The percentages of sperm bound by immunobead-binding and immunofluorescent IgG also correlated ($p < 0.001$).

Value of using husbands' sperm in sperm antibody assays. More men were positive for cytotoxic ($p = 0.03$ in serum and $p = 0.0002$ in seminal plasma) and Immunobead-binding IgA ($p = 0.01$ in seminal plasma only) sperm antibodies against their own sperm than against donors' sperm (Fig. 1). False-negative results were obtained in 18% of women for cytotoxic serum sperm antibodies and 4% to 29% for IgG and IgA Immunobead-binding sperm antibodies in cervical mucus, if husbands' sperm were not used in the tests (Fig. 2).

Correlation between sperm surface immunoglobulins and sperm antibodies in serum or seminal plasma ($n = 28$ couples). There was no correlation between the presence of sperm-surface immunoglobulins and cytotoxic antibodies to husbands' sperm in their serum or seminal plasma, whereas all serum samples with Immunobead-binding IgG, IgA, or IgM were from men with sperm-surface IgG, IgA, or IgM. All men with endogenous IgG, IgA, or IgM had Immunobead-binding sperm antibodies in the seminal plasma, but there were some men with Immunobead-binding an-

*$p < 0.0001$.
†$p < 0.001$.
‡$p < 0.005$.

tibodies in their seminal plasma, lacking endogenous sperm immunoglobulins (Table III).

Percentages of husbands' sperm with IgG on the surface correlated with those carrying sperm-surface IgA ($r = 0.43$; $p < 0.01$, by linear regression analysis) and inversely correlated with seminal plasma cytotoxic sperm antibody titers ($r = -0.41$; $p < 0.01$). Immunobead-binding IgA on the infertile men's sperm was associated with sperm-surface Immunobead-binding IgM ($r = 0.44$; $p < 0.01$). Immunobead-binding IgA to husbands' sperm in the serum correlated with hemagglutinating antibody titers to autologous sperm ($r = 0.47$; $p < 0.01$).

Correlation between sperm antibodies in serum and secretions. Men with serum cytotoxic antibodies and Immunobead-binding IgG to autologous sperm did not always have seminal plasma antibodies to autologous sperm. Conversely, percentage binding of circulating Immunobead-binding IgA to autologous sperm correlated with percentage binding of seminal plasma IgM to autologous sperm ($r = 0.46$; $p < 0.001$) and donors' sperm ($r = 0.43$; $p < 0.01$). The presence of Immunobead-binding IgM to autologous sperm in the serum was associated with the presence of Immunobead-binding IgG to autologous and donors' sperm ($r = 0.55$; $p < 0.001$) in the seminal plasma.

Women with cytotoxic antibodies to their husbands' sperm in the serum were also positive for these antibodies in the cervical mucus ($r = 0.62$; $p < 0.001$, by linear regression analysis of $\log_2$ antibody titers). In women who had serum cytotoxic antibodies to autoimmune husbands' sperm, cervical mucous Immunobead-binding IgA to husbands' sperm was absent ($r = -0.54$; $p < 0.001$, by linear regression analysis of percent binding and $\log_2$ titers). Cervical mucous hemagglutinating antibody titers to husbands' sperm correlated with the serum Immunobead-binding IgA to husbands' sperm ($r = 0.47$; $p < 0.01$).

Correlations between the presence of sperm antibodies in both partners of infertile couples. Wives of infertile men with circulating cytotoxic and hemagglutinating antibodies to autologous sperm had circulating cytotoxic ($r = 0.63$; $p < 0.001$, by linear regression analysis of $\log_2$ titers) and hemagglutinating ($r = 0.54$; $p < 0.001$) antibodies to their autoimmune husbands' sperm. The development of cytotoxic antibodies to husbands' sperm in the cervical mucus of infertile women coincided with the presence of cytotoxic antibodies against autologous sperm in their husbands' seminal plasma ($r = 0.44$; $p < 0.01$).

Percentages of sperm with Immunobead-binding and immunofluorescent IgG antibodies to husbands' sperm in the serum and cervical mucus of infertile women correlated with percent binding of their husbands' seminal plasma Immunobead-binding IgG antibodies to autologous sperm ($r = 0.41$; $p < 0.01$). Se-

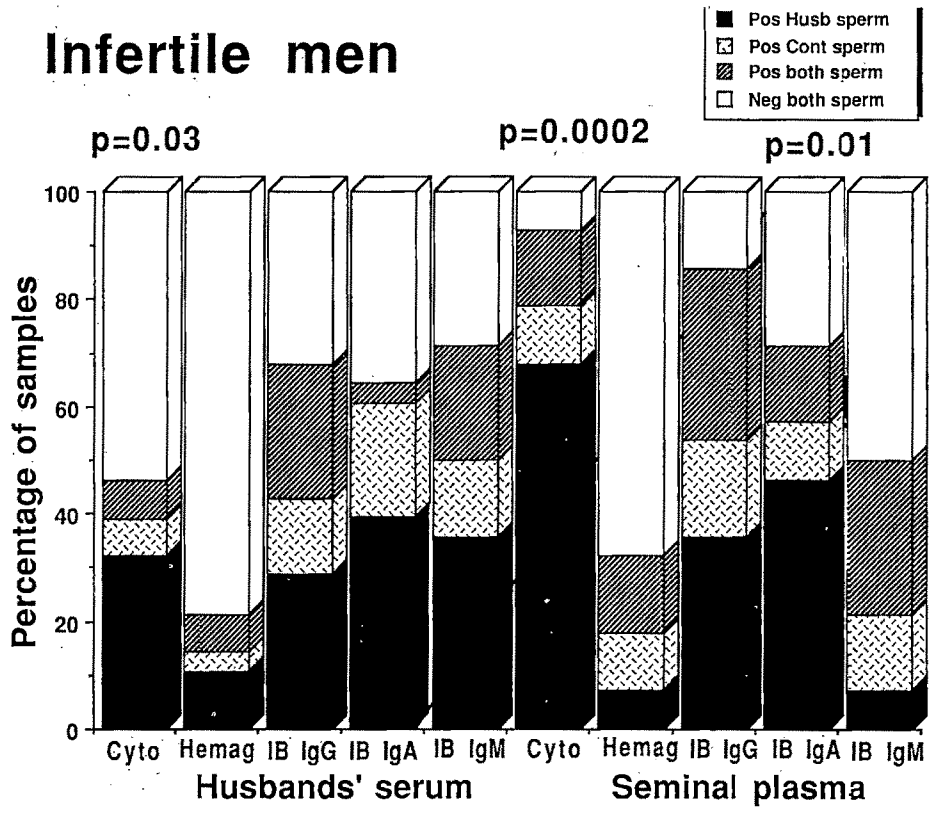

Fig. 1. Percentages of sera and seminal plasma positive for antibodies to autologous or control sperm, or both ($n = 28$).

rum immunofluorescent IgG ($r = 0.56$; $p < 0.001$) and Immunobead-binding IgM ($r = 0.50$; $p < 0.001$) were frequently present in both partners. Infertile women often had Immunobead-binding IgA ($r = 0.41$; $p < 0.01$) or IgM ($r = 0.47$; $p < 0.01$) to husbands' sperm in the serum when these antibodies were present on their husbands' sperm.

All these correlations were observed only in relation to husbands' sperm but not against donors' sperm.

Comment

This study differs from others of a similar nature[1, 2] in that freshly obtained serum, seminal plasma, and cervical mucus from infertile couples were blindly tested against sperm from the same donors by four sperm antibody assays. The data suggest that assays to identify the same isotypes of sperm antibodies correlate reasonably well when sperm from the same donor are used. Because cytotoxic sperm antibodies are primarily IgG,[14] the observed ≥75% agreement in study samples between cytotoxic, Immunobead-binding IgG, and immunofluorescent IgG assays (Tables I and II) is acceptable. However, the correlation is not perfect because the Immunobead-binding and immunofluorescent antibody assays are affected by the specificity, sensitivity, and variability among batches of commercially available antibodies to human immunoglobulin isotypes[15] and because these assays are not yet designed to identify specific subclasses of IgG-mediating cytotoxicity. False-positive results by cytotoxicity assay could hardly have contributed to the discrepancy since samples positive by cytotoxicity assay were also positive by immunofluorescence or Immunobead-binding assays, or both. In addition, ≥90% of samples negative by cytotoxicity were negative by other assays, showing a low incidence of false-negative results by this assay. False-negative results were observed in Immunobead-binding and immunofluorescent IgG assays (Tables I and II). Motile spermatozoa often may avoid being bound with the Immunobeads in contrast to sluggish spermatozoa. Passive hemagglutination and Immunobead-binding and immunofluorescent IgA antibody assays correlated, leading to the surmise that sperm-agglutinating antibodies are essentially IgA.

The study results also emphasize the use of husbands' sperm in sperm antibody assays and support previous reports by our group and others. The cytotoxic sperm antibody assay appears to be most sensitive to antigenic differences between sperm of autoimmune infertile men and nonautoimmune fertile men (Figs. 1 and 2).

These differences may be attributed to the documented presence of special antigens with molecular weights of 30, 43, 58, and 78/80 kd on the sperm of autoimmune infertile men and reactive against IgG.[10] It is possible that these antigens are not involved in eliciting IgM or IgA responses measured by sperm agglutination assays, including passive hemagglutination, Immunobead-binding, or immunofluorescent IgA or IgM (supported by Western blot analysis data from this laboratory).

It may be argued that the presence of endogenous

immunoglobulins on the sperm surface of autoimmune infertile men may lead to false-positive or enhanced results by cytotoxicity and Immunobead-binding assays. The following data refute this point of view: (1) presence of serum or seminal plasma cytotoxic sperm antibodies or seminal plasma Immunobead-binding IgG was independent of the presence of endogenous immunoglobulins (Table III); (2) fewer swim-up sperm used in cytotoxicity and indirect Immunobead-binding assays (≤15% binding) have endogenous immunoglobulins than the entire sperm population pelletted for the direct Immunobead-binding assay (35% to 100%); (3) cytotoxicity assay requires that sperm cell controls without added serum or secretions must have a viability ≥85% for the assay to be valid. The observed differences are therefore a result of sperm antigenic heterogeneity.[5-10] Qualitatively, antibodies against autoimmune men's sperm inhibit sperm motility in the presence of native complement.[16]

Immunobead-binding IgG on the surface of husbands' sperm was associated with endogenous IgA and IgM. Because sperm-surface IgM was also associated with serum Immunobead-binding IgG and serum and seminal plasma IgA sperm antibodies in these men (Table III), it is possible that nonspecific immune responses triggered by infections are detected by the Immunobead-binding assay. In the earlier World Health Organization study, results obtained by Immunobead-binding and agglutination assays correlated with the presence of antibodies to *Mycoplasma* organisms.[17] In this study men with sperm-surface Immunobead-binding IgA were also positive for circulating Immunobead-binding IgM and hemagglutinating sperm antibodies. The primary immune response to microorganisms or viruses in the genital mucosa is IgM- and IgA-mediated and leads to a secondary IgG response. That fewer men were positive for serum Immunobead-binding or immunofluorescent IgM than for seminal plasma IgM sperm antibodies suggests a localized IgM immune response to infection. IgM is known to be present, albeit at low levels, in fresh seminal plasma[18] and is more susceptible to native proteolytic enzyme action than IgG or IgA.[19] Fresh seminal plasma was used in this study and may account for the increased level of detection of IgM in comparison with laboratories that use stored frozen seminal plasma samples.

Our data also suggest that development of autoimmunity to sperm in infertile men may be heterogeneous. Infertile men with cytotoxic, Immunobead-binding, and immunofluorescent IgG antibodies to autologous sperm in the serum and seminal plasma may be genetically prone to produce these antibodies, whereas after infections other men may develop transient sperm antibodies in the seminal plasma but not in the serum. The sperm motion characteristics of the latter are normal in contrast to the critically affected sperm motion characteristics of infertile men with true autoimmunity to sperm in serum and seminal plasma.[20]

Unlike their husbands, the wives of autoimmune infertile men had sperm antibodies in both serum and cervical mucus. Women exposed to the unique sperm antigens of their autoimmune infertile husbands[10] or to an excess of antigens generated through degradation of infected sperm in their husbands may have cervical mucous sperm antibodies. Circulating sperm antibodies may develop in these women as a result of transudation of cervical mucous sperm antibodies or postcoital soluble sperm antigens from their husbands. Serum Immunobead-binding IgA to husbands' sperm developed in women whose husbands had sperm-surface Immunobead-binding IgA and IgM. The latter couples might have sperm antibodies as a result of infections in the husbands.

It has been shown[1, 5, 7-9] that cytotoxic, immobilizing, and hemagglutinating sperm antibodies in the serum and secretions of both partners in infertile couples correlate with each other; this was substantiated by this study. In most instances this correlation was in immune responses of both partners, specifically against sperm from autoimmune infertile husbands, reemphasizing the need to use husbands' sperm in these sperm antibody assays.

Sperm-immobilizing and cytotoxic antibodies are sperm specific and may be better correlated with infertility than sperm-agglutinating antibodies.[21] Immunobead-binding and immunofluorescence assays identify the isotypes of sperm-reactive antibodies.[11, 12, 15] The combination of an assay to evaluate sperm immobilizing function and another assay that enumerates the isotype of immunoglobulins appears preferable to use of a single assay because such an approach yields information on the immunoglobulin isotype and its functional significance. For example, cytotoxic sperm antibodies, singly or in combination with Immunobead-binding or immunofluorescent IgG, denote the presence of true immunity to sperm, whereas the presence of Immunobead-binding or immunofluorescent IgG, IgA, or IgM in absence of cytotoxic sperm antibodies may imply nonspecific infection-related antibodies. Whereas corticosteroid therapy is desirable for the former, antibiotic therapy would seem appropriate for the latter.

It is concluded (1) that cytotoxicity, Immunobead-binding (IgG), and immunofluorescence (IgG) assays are in agreement when sperm from the same donors

are used, (2) that a significant incidence of false-negative results could occur especially in infertile men, when husbands' sperm are not used; (3) that the women's isoimmunity to sperm is associated with their husbands' autoimmunity to sperm.

We thank H. Oliver Williamson, MD, Chief, Section of Reproductive Endocrinology and Infertility and Vice Chairman, Obstetrics and Gynecology Department, for providing the clinical samples and reviewing the manuscript.

Extensive vulvar and vaginal varicella necessitating abdominal delivery

Cynthia K. Sites, MD, David M. Sherer, MD, David L. Gandell, MD, and James R. Woods, Jr., MD
Rochester, New York

Maternal varicella occurs in fewer than five per 10,000 pregnancies in the United States. A case is reported in which markedly painful, extensive vulvar and vaginal ulcers prevented cervical examination, and cesarean section was performed with the patient under general anesthesia. (AM J OBSTET GYNECOL 1990;163:1630-1.)

Key words: Varicella-zoster, chickenpox, abdominal delivery

The rash of varicella-zoster usually begins on the face or scalp and progresses rapidly to the trunk, often sparing the extremities. Lesions begin as macules and papules and evolve to pustules and crusts, with completion of the cycle in 8 to 12 hours. Lesions can also develop in mucous membranes, including the mouth and vagina. These appear as vesicles that rupture quickly, leaving shallow ulcers. We report a case where a patient exposed to varicella early in pregnancy received varicella-zoster immune globulin but extensive vulvar and vaginal varicella at term necessitated abdominal delivery.

Case report

A 32-year-old white woman, gravida 3, para 2, was admitted to the labor and delivery suite with mild irregular contractions at 41⅐ weeks' gestation. A nonstress test that day was reactive, but a marked decrease in amniotic fluid was noted by ultrasonography.

At 7 weeks into the current gestation, she had received five vials of varicella-zoster immune globulin 9 days after exposure to chickenpox. Gestational diabetes was well controlled by diet. Her history was negative for genital herpes.

Eight days before admission, she first noted fever, malaise, and occasional coughing. The next day fever, shaking chills, and a rash typical of varicella were seen. To her knowledge, she had not been reexposed to varicella.

On admission she was afebrile, with blood pressure 110/76 mm Hg and pulse 80 beats/min. Examination of the mouth revealed a few ulcers. Results of heart and lung examination were normal. Abdominal examination revealed a fundal height of 35 cm, with a vertex-presenting fetus that had a normal fetal heart rate. Extremities, face, trunk, and abdomen were covered with lesions that were mostly crusted but in various stages of healing (Fig. 1). Cervical examination was intolerable for the patient because of multiple painful vulvar and vaginal ulcers (Fig. 2). On initial examination the cervix was 1 to 2 cm dilated and 50% effaced, and the vertex was at the −3 station. A chest x-ray film showed no evidence of varicella pneumonia.

Because of the gestational age in conjunction with olighohydramnios in a patient with gestational diabetes, delivery was elected. Options for delivery were discussed with the patient and included intravenous oxytocin induction of labor with anesthesia, waiting for more healing before attempting vaginal delivery, or cesarean section. Members of anesthesiology, perinatology, and neonatology departments were consulted. Because of the skin lesions on the back, spinal or epidural anesthesia was thought to be a high-risk factor for meningitis. Since even gentle touching of the vaginal lesions caused great discomfort for the patient, the decision was made to perform a cesarean section while she was under general anesthesia. A female infant weighing 3205 gm was delivered with Apgar scores of 7 and 8 at 1 minute and 5 minutes, respectively.

The infant did not receive varicella-zoster immune globulin, because the pediatric infectious disease team thought that, because maternal symptoms appeared more than 5 days before delivery, maternal antibodies had formed and had been passively transferred to the infant. The mother and infant were both discharged in good health 5 days after delivery. In the infant a mild rash suggestive of varicella developed several days later.

Comment

It is uncertain how our patient contracted chickenpox. Enders[1] has shown that varicella-zoster immune

Fig. 2. Extensive perineal varicella lesions.

globulin, when given within 96 hours of exposure, is protective in 80% of cases in 25 seronegative patients. Varicella developed in approximately 90% of 18 women who did not receive varicella-zoster immune globulin. Nine patients who received varicella-zoster immune globulin >96 hours after chickenpox exposure had an attenuated form of the disease. Because our patient received varicella-zoster immune globulin >96 hours after exposure at 7 weeks' gestation, it is possible that varicella-zoster immune globulin delayed expression of the disease. Alternatively, she could have been reexposed unknowingly.

To our knowledge, this is the first reported cesarean section performed because of extensive vulvar and vaginal varicella ulcerations. We do not suggest that peripartum maternal varicella is in itself an indication for cesarean section for fetal or maternal reasons. However, this case represents a rare maternal genital manifestation of varicella precluding vaginal delivery because of exquisitely painful lesions in a patient in whom delivery was deemed necessary, with regional anesthesia contraindicated. Steyn and Odendaal[2] reported a case of a primigravid woman with varicella pneumonia at 33 weeks' gestation with repetitive late fetal heart rate decelerations. Labor was suppressed, with subsequent improvement of maternal and fetal conditions. The patient subsequently underwent a cesarean section because of breech presentation with good outcome.

The role of fetal membranes in regulating production, transport, and metabolism of prostaglandin E_2 during labor

John A. McCoshen, PhD,[a] Dennis R. Hoffman, PhD,[b] Jeremy V. Kredentser, MD,[a] Carolina Araneda,[a] and John M. Johnston, PhD[b]

Winnipeg, Manitoba, Canada, and Dallas, Texas

The level of prostaglandin E_2, a potent stimulator of myometrial contractions, increases in amniotic fluid during labor. We tested whether amniotic prostaglandin E_2 crosses the reflected fetal membranes to the myometrium during labor. Disks of amnion, chorion-decidua, and amnion chorion-decidua from 10 term pregnancies before labor and nine vaginal deliveries after normal spontaneous labor were incubated in two-sided perfusion chambers in the absence or presence of 1 μmol/L indomethacin, or in the presence of a bolus of prostaglandin E_2 and radiolabeled prostaglandin E_2 added to the fetal chamber. Net amniotic prostaglandin E_2 increased significantly ($p = 0.003$) after labor. However, there was no significant difference in prostaglandin E_2 concentrations on the maternal side of amnion chorion-decidua between labor conditions. High-pressure liquid chromatography identified the transport of intact tritiated prostaglandin E_2 across amnion but not across chorion-decidua or amnion chorion-decidua in which prostaglandin E_2 was completely metabolized. Because of 15-hydroxyprostaglandin dehydrogenase activity in chorion, we suggest that amniotic prostaglandin E_2 transport to the myometrium is impaired. Thus the increase in prostaglandin E_2 production that occurs in amnion tissue after labor commences does not result in an increase in prostaglandin E_2 concentration on the myometrial side of the fetal membranes in the in vitro preparation. (Am J Obstet Gynecol 1990;163:1632-40.)

Key words: Fetal membranes, prostaglandin E_2 metabolism, labor

Prostaglandins of fetal origin are believed to be important factors in regulating myometrial contractions and the events of labor.[1, 2] During labor the substantial increase in the concentration of prostaglandin E_2 (PGE_2) in amniotic fluid[1, 3] appears to result from an elevated production of PGE_2 by amniotic membrane lining the gestational sac,[4, 5] as a result of increased activities of the enzymes responsible for release of arachidonic acid[2] and prostaglandin synthesis.[2] This progressive accumulation of PGE_2 in amniotic fluid poses a potential for increased availability of PGE_2 to myometrium by translocation across the fetal membranes.[3, 6] However, this concept is complicated by the observations that (1) intact reflected membranes, consisting of adherent amnion plus chorion-decidua obtained from women after the spontaneous onset of labor, display increased PGE_2 output on the amniotic surface but not on the maternal surface facing the myometrium,[7] and (2) chorion laeve lying between amnion and decidua possesses high 15-hydroxyprostaglandin dehydrogenase activity capable of metabolizing PGE_2.[1] Decidual tissue also has the capacity to snythesize, secrete, and metabolize PGE_2 and prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$)[1, 2] and appearance of PGE_2 on the maternal side of the fetal membranes may not necessitate solely an amniotic source. This study was performed to determine the translocation of PGE_2 from fetal to maternal compartments and to examine the metabolism of the prostanoid during transit.

Material and methods

Placentas were collected from 10 clinically normal women at term (38 to 40 weeks) after delivery by elective repeat cesarean section but before labor onset (prelabor). A second group of samples was obtained from nine normal women who were delivered vaginally at term following the spontaneous onset of labor (postlabor). Tissues were immediately taken to the laboratory and rinsed in cold (4° C) phosphate-buffered saline solution (pH 7.4) to remove residual blood. After reflected membranes were severed from the placenta, 12

6/1/24036

discs of intact membrane (approximately 8 cm^2) were cut from each tissue. Subsequently, different membrane combinations were prepared to include four disks each of amnion, chorion-decidua, and intact membrane.

Reflected fetal membrane is a composite of amnion fused to smooth chorion (chorion laeve). After separation from the uterus, a thin layer of decidua usually remains adherent to the maternal surface of chorion. Thus the term *chorion-decidua* best describes the chorionic layer of the membranes after this separation from the uterus. The amniotic component of reflected membranes is fused to the chorion-decidua. Thus, for purposes of simplifying the terminology, "intact" membranes will be used hereafter to designate amnion plus chorion-decidua.

Each disk of tissue was mounted inside a dual-compartment perfusion chamber described previously.[7] The chambers were checked over a 10-minute period to ensure that the preparations were free of leaks. During incubation constant circulation and continuous aeration with filtered humidified air were maintained in the chambers. Synthetic amniotic fluid[8] at pH 7.4 was added to the chambers (9 ml each) on the fetal and maternal sides of suspended tissue and preincubated at 20° C for 2 hours with a change of medium after each hour. By this procedure endogenous PGE_2 secretion caused by the initial trauma was eluted and the preparation was stabilized.[9] After the second change of medium, the chambers were placed in a water bath at 37° C and allowed to equilibrate to ambient temperature over 15 minutes. The time point after equilibration was designated as 0 hours. The experimental regimen for each membrane type from each patient included control membranes incubated in medium alone, membranes incubated in the presence of 1 μmol/L indomethacin, membranes in which a bolus of PGE_2 (final concentration = 6.0 nmol/L) was added to the fetal chamber, and a fourth membrane incubated in medium containing 1 μmol/L indomethacin plus a bolus of PGE_2 on the fetal side. Thus for each membrane type from each patient determinations were made for PGE_2 production, inhibition of PGE_2 production, PGE_2 transport from the fetal to maternal surfaces, and PGE_2 transport during inhibition of PGE_2 production. Table I summarizes the variables used in the experimental design.

Samples of 0.5 ml were removed from the fetal and maternal chambers at 1 and 2 hours of the preincubation period and at 0, 2, and 4 hours from initiation of the experiment. PGE_2 values were corrected for the fixed loss of media volume as a result of sampling. Radioimmunoassay (RIA) of PGE_2 was performed as previously described.[10] The interassay variation was 10% and the intraassay variation was <8%.

Treatments
Control
Plus 1 μmol/L indomethacin (both sides)
Plus PGE_2 bolus (fetal side only)
Plus indomethacin (both sides) and PGE_2 bolus (fetal side only)

Separate experiments were performed on normal tissues obtained from each of five women before labor and after labor, whereby 0.21 pmol of [^{3}H]PGE_2 (0.03 μCi, >98.4% purity) was added to the fetal side of either the amnion, chorion-decidua, or intact membranes at 0 hours after preequilibration. Samples (0.1 ml) were removed from the fetal and maternal sides at 0, 2, and 4 hours of incubation at 37° C and total counts per minute were assessed by liquid scintillation counting. Comparisons were then made between the results of RIA for PGE_2 and the extent to which tritiated compound(s) appeared in the maternal compartment.

Additional aliquots of media were used for determination of radioactivity in various prostaglandins and their metabolites. The individual prostanoids were separated by high-pressure liquid chromatography (HPLC) according to Campbell and Ojeda.[11] Briefly, PGE_2, 15-keto-PGE_2, and 15-keto-dihydro-PGE_2 (5 μg each) carrier was added to 3 to 5 ml of sample; the samples were acidified and passed through a Bondelut octadecylsilyl column. The prostaglandins were eluted with ethyl acetate. The prostaglandins were then fractionated on a Dupont 850 liquid chromatograph fitted with an Alltech Econosphere C18 reverse-phase column (250 mm × 4.6 mm × 5 μm) eluted with 68% phosphoric acid (25 mmol)/L acetonitrile for 40 minutes and a linear gradient to 100% acetonitrile for 20 minutes. Optical density was monitored at 192 nm; radioactivity was quantitated with a Radiomatic Flo-One radioactivity flow detector.

All results were statistically evaluated by a general linear model analysis of variance, individual paired and

unpaired two-tailed t tests, simple and multiple regression, and correlation analyses.

Results

Net PGE_2 production by control membranes was calculated by subtraction of PGE_2 elution in the presence of indomethacin from PGE_2 production in incubation medium alone. The results are summarized in Fig. 1. A comparison of each membrane type by general linear model analysis of variance of membrane side and condition of labor identified a significant increase in net postlabor PGE_2 production by the fetal side of intact membrane ($F = 5.72; p = 0.02$) and both fetal and maternal sides of postlabor amnion ($F = 9.72; p = 0.003$). Chorion-decidua displayed no change in PGE_2 production between prelabor and postlabor conditions on either the fetal or maternal sides.

The addition of PGE_2 at 0 hours to the fetal side of each membrane type incubated in the presence of indomethacin resulted in a progressive decline in PGE_2 on the fetal side of all membranes obtained from both prelabor and postlabor deliveries (Fig. 2). However, a concomitant increase in PGE_2 on the maternal side was observed only when amnion was used (Fig. 2, *C*). No change in PGE_2 concentrations over baseline levels was detected on the maternal sides of the intact membranes or chorion-decidua preparations (Fig. 2, *A* and *B*). The amounts of PGE_2 recovered at 4 hours on the fetal and maternal sides of each membrane preparation from the above experiments were compared with the concentration of PGE_2 added to the fetal chamber at 0 time (Table II). When the individual membrane types were compared in the amount, percentage or both of recoverable PGE_2 between prelabor and postlabor conditions, no significant difference was observed. However, comparison between membrane preparations within each condition of labor revealed highly significant ($p < 0.001$) differences in recoverable PGE_2. The data from amnion indicated that 24% to 26% of PGE_2 is transported from the fetal to maternal side over 4 hours. However, it was not evident from these experiments that PGE_2 was translocated by chorionic membrane. From the decline in PGE_2 on the fetal side of chorion-decidua and intact membrane and failure of PGE_2 appearance on the maternal side, it can be computed that after 4 hours, chorionic metabolism of PGE_2 accounts for between 33% and 56% of the exogenously added prostanoid to PGE_2 metabolites. Furthermore, addition of a bolus of PGE_2 to the fetal side of intact membrane at time 0 and incubated without any prostaglandin synthetase inhibitor present resulted in PGE_2 concentrations on the maternal side after 4 hours of 0.41 ± 0.18 pmol/ml before

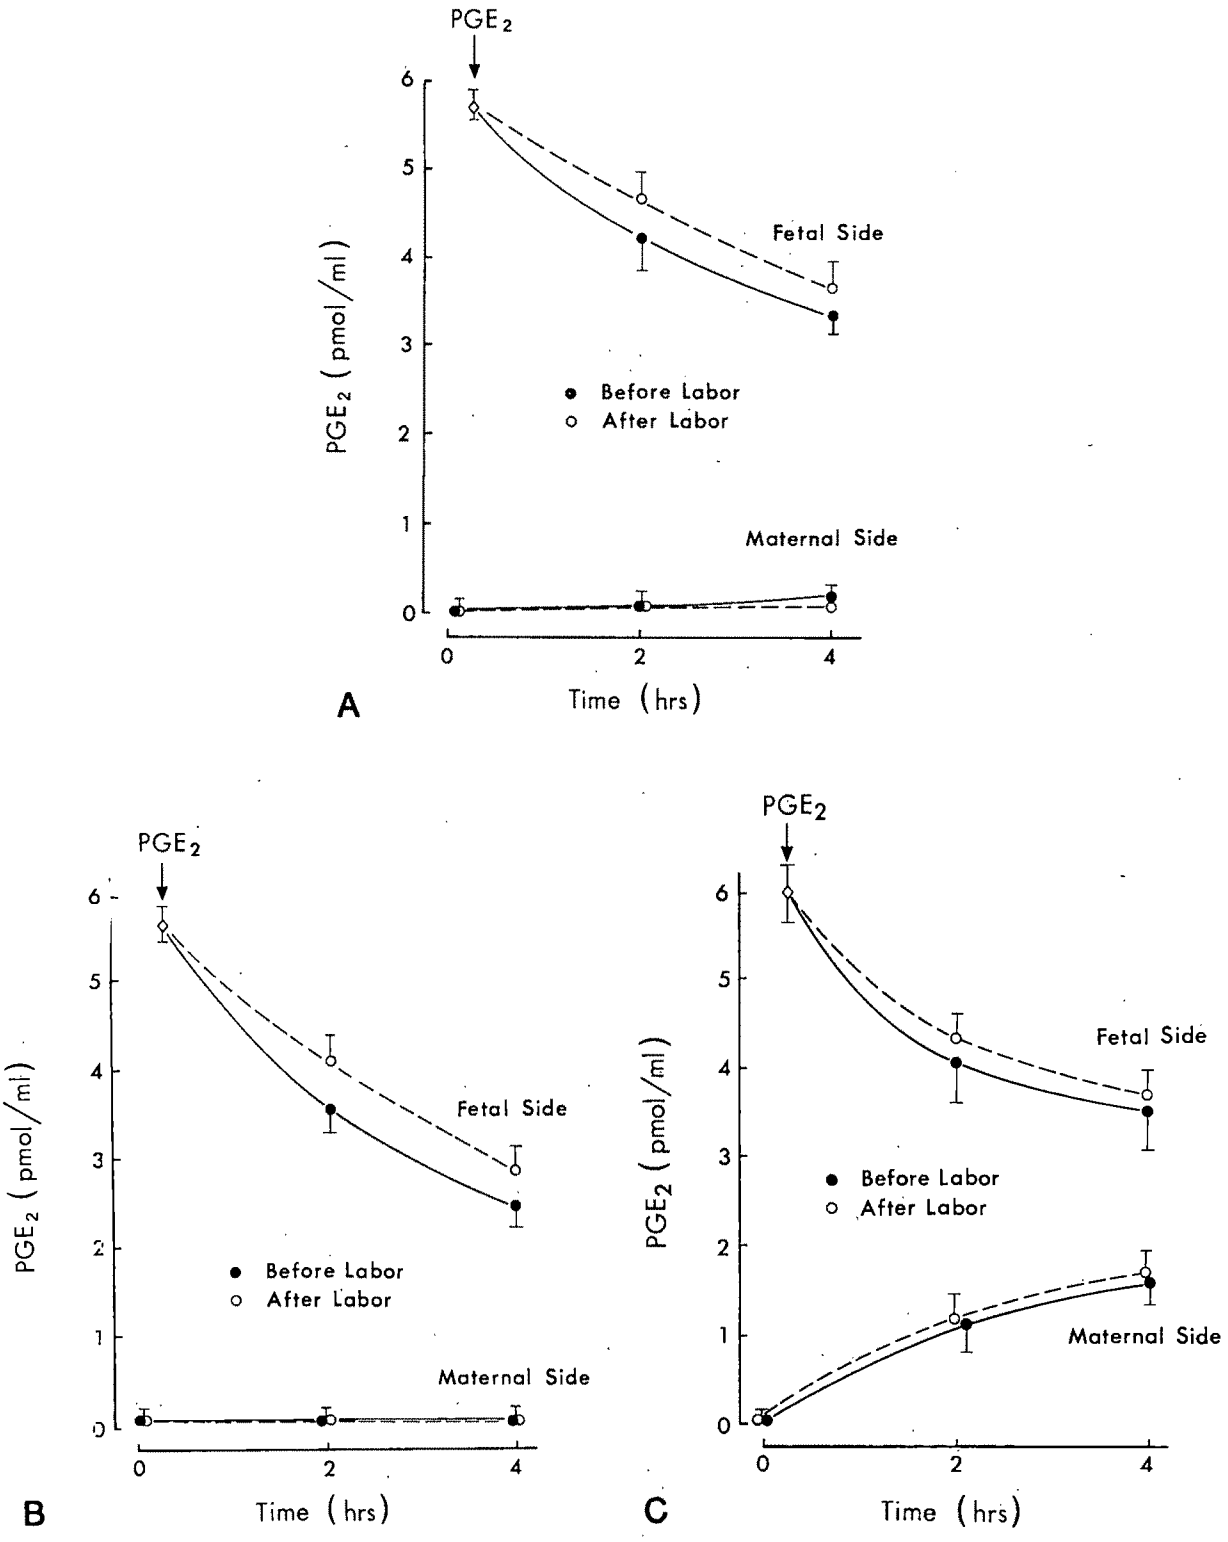

Fig. 2. Translocation of PGE_2 across amnion chorion-decidua (intact) **(A)**, chorion-decidua **(B)**, and amnion **(C)** after indomethacin (1 μmol/L) treatment and bolus PGE_2 (6 nmol/L). Membranes were from before labor (n = 10) and after labor (n = 9). Values are mean ± SEM.

labor and 1.16 ± 0.56 pmol/ml after labor (mean ± SEM); the values were not significantly different. Similarly, the PGE_2 concentrations on the maternal side of control intact membranes (no PGE_2 or indomethacin added) before labor were 0.51 ± 0.27 pmol/ml and 1.21 ± 0.54 pmol/ml after labor. The same experiment with chorion-decidua resulted in no change in PGE_2 concentrations on the maternal side over those of

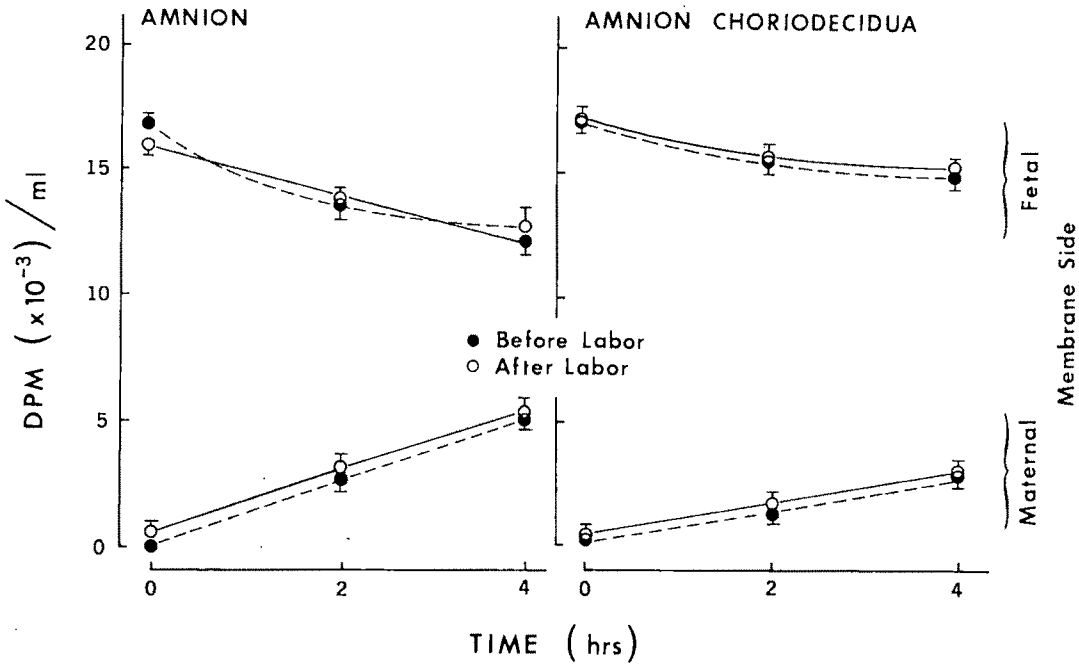

Fig. 3. Translocation of radiolabeled PGE_2 and metabolites across amnion and amnion-chorion-decidua from before ($n = 5$) and after ($n = 5$) labor delivery. [^{3}H]PGE_2 was added at time 0 to fetal chamber of perfusion apparatus. Values represent means ± SEM.

chorion-decidua controls (data not shown). Thus, despite maintenance of high PGE_2 levels on the fetal side of intact and chorion-decidua membranes, we found no evidence of PGE_2 translocation to maternal side.

To further characterize PGE_2 metabolism, [^{3}H]PGE_2 was added to the amnion and intact membrane preparations, and the metabolic products in the fetal and maternal compartments were identified by HPLC (Fig. 3). When amnion was used and [^{3}H]PGE_2 was placed on the fetal side, approximately 30% of added radioactivity was translocated to the maternal side after 4 hours. When the intact membrane preparation was used, approximately 15% of tritium translocated to the maternal chamber by 4 hours. There was no significant difference in translocation or acccumulation of tritium in membranes relative to labor status. Results of HPLC

analysis of tritiated compounds in fluids from the fetal and maternal chambers of amnion and intact membrane are summarized in Tables III and IV. Approximately 25% of the radioactivity was found in the maternal chamber after a 4-hour incubation with the before-labor amnion and 27% with the after-labor amnion. This radioactivity comigrated with authentic PGE_2 on the HPLC. This value is similar to the PGE recovery by RIA analysis (Table III). The analyses of intact membrane incubates failed to identify any [^{3}H]PGE_2 on the maternal side, whereas 55% to 57% of compound on the fetal side was [^{3}H]PGE_2. Tritium recovery from the HPLC columns was 96.3% and 82.6% for amnion and intact membrane, respectively. The major metabolite in the maternal chamber of intact membranes was 15-keto-13,14-dihydro-PGE_2 both before and after labor; concentrations were 52.1% and 40.3%, respectively. Additional PGE_2 metabolites coeluted with authentic 15-keto-PGE_2 and the bicyclic derivative of the 15-keto-13,14-dihydro-PGE_2 (Fig. 4). However, no radiolabeled PGE_2 could be detected on the maternal side when the intact membrane preparation was used. Less than 0.5% of the added total radioactivity was present in the tissue after the 4-hour incubation. Therefore the radioactivity of the tissues was not further fractionated into the various metabolites of PGE_2.

Comment

On the basis of reported findings, it is suggested that PGE_2 can be translocated across isolated amnion. However, the translocation of exogenously added PGE_2 across the chorion-decidua appears to be impeded by enzymatic metabolism of PGE_2 in this tissue. Earlier

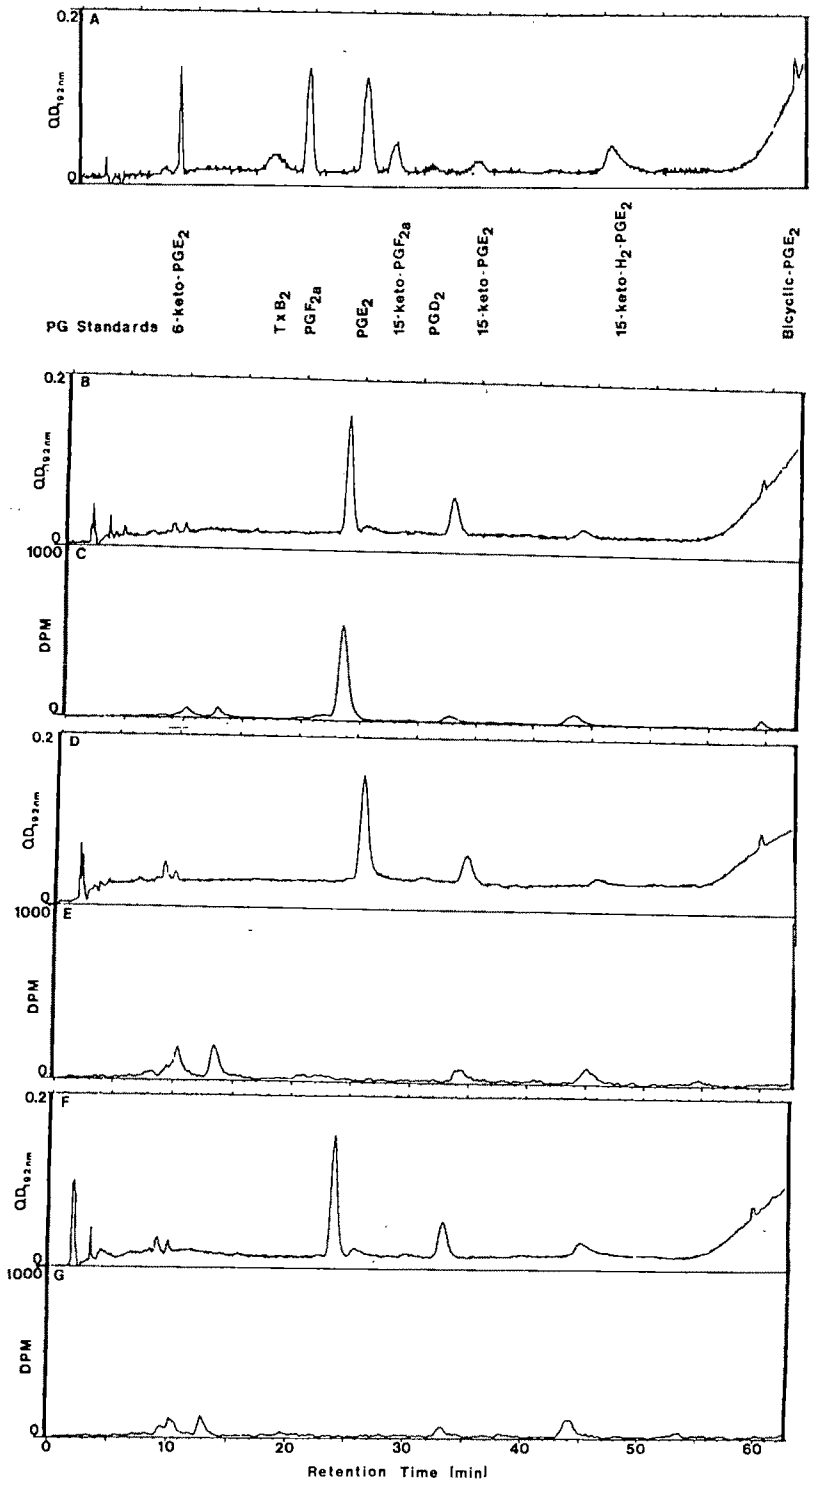

Fig. 4. Representative HPLC fractionations of prostaglandins *(A, B, D, F)* detected at 192 nm and associated radioactivity *(C, E, G)* after [^{3}H]PGE_2 bolus to fetal side of membranes. *A*, Separation of authentic prostaglandin standards; tritium in fetal *(B, C)* and maternal *(D, E)* chambers at 4 hours of "before labor" intact membrane preparation; tritium in maternal chamber at 4 hours of "after labor" intact membrane preparation *(F, G)*. studies identified the capacity of chorion laeve to metabolize PGE_2.[1,2] Amnion tissue has a high capacity for PGE_2 synthesis and a limited capacity to inactivate PGE_2 because of the absence of 15-hydroxyprostaglandin dehydrogenase activity.[1,2] We and others[1,2] have observed that chorion laeve and decidua vera tissues also have the capacity for the synthesis of both PGE_2 and $PGF_{2\alpha}$.[1,2] In addition, these two latter tissues have a

significant amount of prostaglandin dehydrogenase activity.[1, 2] The present observations on the translocation of PGE_2 are consistent with these enzymatic studies in that both endogenously synthesized and the exogenously added PGE_2 were translocated across the amnion membrane unchanged, whereas PGE_2 was metabolized completely when intact membranes were used. Recently Nakla et al.[6] and Bennett et al.[12] suggested that most amniotic PGE_2 translocates unmetabolized across amnion-chorion plus decidua. However, our results confirm earlier observations that PGE_2 concentrations do not increase on the maternal side of isolated chorion-decidua or intact membrane despite increased amniotic output after labor.[7] Furthermore, our HPLC analysis failed to identify any unmetabolized [^{3}H]PGE_2 on the maternal side of intact membrane regardless of labor status, and RIA of PGE_2 also failed to detect any increase on the maternal side despite a substantial loss of added PGE_2 on the fetal side. Each membrane preparation used in our study was confirmed to be leak-free, and the incubation medium we used is known to maintain cellular integrity of the fetal membranes.[8] Furthermore, Fig. 3 clearly identifies translocation of tritiated compound across the membranes, confirming that there was no blockage of diffusion in our system.[7, 9] More recently, Collins and Roberts[13] also failed to identify transfer of amniotic fluid PGE_2 from the fetal to maternal side of intact fetal membrane despite increased PGE_2 synthesis in amnion. The disparate results between the various groups with regard to the PGE_2 translocation across the fetal membranes is not readily apparent. However, on the basis of our data, it is suggested that amnion is not the source of PGE_2 on the myometrial side of reflected membrane during labor. It should be emphasized that these findings do not discount the potential for activation of amnion by prostanoids or other autacoids which, in turn, activates the adjacent chorion in labor-related metabolic events.

We have suggested that a second autacoid, namely platelet-activating factor, may indeed function by such a mechanism.[14] Platelet-activating factor has been reported to activate glycogen breakdown in the perfused rat liver.[15] Furthermore, platelet-activating factor levels in term amnion before labor are equivalent to amnion from early gestation (14 to 16 weeks) but twofold greater in postlabor amnion. In addition there is an in vitro platelet-activating factor–induced efflux of PGE_2 by term amnion[14] and amnion cells in culture.[16] Similar to PGE_2, platelet-activating factor concentrations in amniotic fluid are markedly elevated during labor at term[14] and in both preterm labor and premature rupture of membranes.[17] Recently we reported that the wet weight of reflected amnion increased with labor and that this may result from the hydrolysis of the thick underlying collagen layer in preparation for membrane rupture and disociation from the uterus at parturition.[9] In addition, prostaglandin-mediated collagenase activity is reported to occur in the follicular wall before its rupture at time of ovulation, and cervical effacement caused by collagen breakdown can be induced by PGE_2.[18] Thus increased amnionic PGE_2 synthesis may serve other currently undefined functions in labor and parturition.

Failure of amniotic PGE_2 to reach the myometrial surface of the reflected membranes does not negate the presence of the prostanoid in such tissue. The control experiments clearly identify PGE_2 production on the decidual surface of the membranes. However, we were unable to identify any significant increase in PGE_2 production on the maternal surface despite a substantial increase in amniotic productivity after labor. This is similar to our previous observations.[7] Thus we suggest that the availability of PGE_2 per se on the maternal surface of the membranes is steady during labor and independent of PGE_2 productivity by amnion.

Because both decidua and myometrium produce PGE_2,[1, 2] availability of PGE_2 in the myometrium may be exclusively maternal in origin. Furthermore, a role for PGE_2 in contractility may be at the level of prostaglandin receptors on myometrial cells. However, myometrial receptors for PGE series and $PGF_{2\alpha}$ appear quantitatively equivalent before and after labor.[19] Furthermore, myometrium converts PGE_2 to $PGF_{2\alpha}$, and to 13,14-dihydro-15-oxo metabolites on both prostaglandins at an equivalent rate before and after labor.[20] Thus PGE_2 production and metabolism by chorion, decidua, and myometrium appear to be unaffected by labor. Conversely, $PGF_{2\alpha}$ production by the decidua[21] and the decidual surface of intact fetal membrane[22] is reported to increase with labor. In maternal circulation, the concentration of PGF metabolites rises substantially during labor, whereas PGE metabolite concentrations are not altered.[1] Because the rates of production of PGE_2 by intact fetal membrane increase with labor only on the fetal side and that of $PGF_{2\alpha}$ only on the maternal side, respectively, we suggest that dynamic changes in the ratio of PGE_2 to $PGF_{2\alpha}$ by each of amnion, chorion, and probably decidua are important to the process of labor. A change in prostaglandin ratios may impart a synergistic effect that positively influences myometrial contraction. Other prostanoids and autacoids such as platelet-activating factor, probably play an important role in maintaining the contractions of labor.[14]

In summary, the results of these experiments suggest that PGE_2 of amnionic origin is unavailable to the myometrium because of its metabolism by the underlying chorion. Thus PGE_2 alone may not be the sole initiating factor of labor because its availability on the maternal surface appears not to change between prelabor and postlabor conditions. Thus we suggest that a fundamental process such as labor is more likely the result of multiple factors rather than the so-called "trigger" hypothesis involving a single compound, as invoked by some investigators.

We greatly appreciate the expert technical assistance of Ms. Collette Odowichuk, Ron White, and Catherine Robinson during these experiments.

Surgical staples in cesarean section: A randomized controlled trial

Marc G. Villeneuve, MD, Samir Khalifé, MD, Sylvie Marcoux, MD, PhD, and Pierre Blanchet, MD

Sainte-Foy, Quebec, Canada

This randomized controlled trial compares the use of the Auto Suture Poly CS 57 disposable surgical stapler (n = 98) with standard hysterotomy (n = 102) in low transverse cesarean sections. Subjective assessment of blood loss by the surgeon resulted in lower mean (±SEM) total blood loss estimates in the stapled group (492 ± 24 ml) than in the nonstapled group (579 ± 38 ml) (p = 0.05). However, surgeon's estimation of blood loss as a result of the hysterotomy and blood loss estimated by the hemoglobin deficit measured on the second postoperative day did not significantly differ between the two groups. The use of the stapling device tended to lengthen the total operating time, which averaged 42.5 minutes in the group with the staples and 39.2 minutes in the group with the standard hysterotomy (p = 0.05). The risk of febrile morbidity, the frequency of endometritis, and the length of hospitalization were similar in the two groups. Our results do not support the routine use of the Auto Suture Poly CS 57 disposable surgical stapler in low transverse cesarean sections. (Am J Obstet Gynecol 1990;163:1641-6.)

Key words: Absorbable staples, cesarean section

The Auto Suture Company has marketed the Auto Suture Poly CS* 57 disposable surgical stapler with a disposable loading unit of copolymer Lactomer* absorbable staples. The loading units cost approximately $200 per patient. This device has gained acceptance in many surgical specialties. Unlike the original stapling device with metal staples,[1, 2] the use of the Lactomer absorbable surgical staples for hysterotomy has been shown not to impair subsequent fertility in nonhuman primates.[3] It has therefore been suggested that this stapling device could be used as an alternative to the standard hysterotomy procedure in human cesarean section.

The Auto Suture Poly CS 57 disposable surgical stapler could offer advantages over the standard hysterotomy procedure. First, the stapling device was designed to reduce the amount of bleeding caused by the hysterotomy and hence should lower the risk of transfusion-related complications. Second, the inert copolymer staples do not compromise the microcirculation of the uterine wall as much as the absorbable sutures do, leading to less inflammation and less ischemia in the uterine healing process. These two characteristics should diminish the risk of infection and favor a more resistant hysterotomy healing for subsequent vaginal deliveries. The less inflammation in the vesicouterine space, the less adherent will be the bladder to the lower uterine segment in the event of a repeat cesarean section. Furthermore, if the Auto Suture Poly CS 57 disposable surgical stapler could reduce the frequency of endometritis after a cesarean section, as recently suggested by Burkett et al.,[4] then hospital stay and costs could be lowered too. Finally, by reducing bleeding the Auto Suture Poly CS 57 disposable surgical stapler could shorten operating time.

To our knowledge, only one previous study has evaluated the use of surgical staples for cesarean section in human beings,[4] and it was not a randomized controlled trial. The purpose of our study was to assess whether performance of a low transverse hysterotomy with the Auto Suture Poly CS 57 disposable surgical stapler in cesarean section, in comparison with a standard hysterotomy procedure, reduces blood loss, operating time, febrile morbidity, and length of postoperative hospitalization.

Material and methods

The study was carried out at Saint-Sacrement Hospital, a hospital affiliated with Laval University in Quebec City, Quebec, Canada. All patients who needed a cesarean section from Nov. 18, 1987, to April 14, 1989, were eligible for the study. Patients who agreed to par-

ticipate signed an informed consent form. The study was approved by the hospital's ethics committee. Women enrolled in the study were randomly allocated to one of two hysterotomy techniques: hysterotomy with the Auto Suture Poly CS 57 disposable surgical stapler or standard hysterotomy. The allocation scheme was generated with a table of random numbers and the randomization was achieved with a series of sealed numbered envelopes.

All cesarean sections were performed by the attending physician and a resident. The whole procedure was the same for the two groups except for the hysterotomy technique. In the group with the standard technique, the lower uterine segment was incised with a scalpel on a distance of 2 cm after the bladder was reclined downward. The incision was extended bilaterally in a transverse fashion with bandage scissors or by digital traction. In the group with the stapler, a 2-cm hysterotomy incision was made with a scalpel in the lower uterine segment. The stapling device (Fig. 1) was then introduced between the membranes and the uterine wall with its distal end pointed laterally and slightly upward. The stapler was then fired, which caused two columns of eight absorbable staples each to be applied parallel to the lower uterine segment. As the staples were closed, a cutting device was then activated and the hysterotomy was performed between the two rows of staples. The same procedure was repeated on the other side. The membranes were ruptured and the infant was delivered. Extreme caution was taken not to include any fetal parts or umbilical cord in the stapling device. Once the placenta was delivered, the hysterotomy was closed with a single layer of absorbable chromic catgut suture 0, taking care to symmetrically appose the two rows of staples. This continuous nonlocked suture was passed through the middle of each staple starting at the lateral extremity on each side of the hysterotomy and ending at the center.

Antibiotic prophylaxis was given to all patients who had been in labor for >6 hours or had their membranes ruptured for >6 hours. Prophylaxis consisted of intravenous administration of cefazolin 1 gm or cefoxitin 2 gm at the time the umbilical cord was clamped. During the procedure the nursing staff systematically recorded the operating time. Different time spans were calculated: time from abdominal wall incision to birth, time from opening of the uterus to uterine closure, and total operating time from abdominal wall incision to abdominal wall closure.

Immediately after the cesarean section the surgeon recorded his/her subjective assessment of total blood loss and his/her assessment of blood loss attributed to the hysterotomy. Technical difficulties or complications related to the use of the stapling device were also noted.

The coagulation parameters (prothrombin time, partial thromboplastin time, and bleeding time) and the hemoglobin value were obtained for all patients before the cesarean section. The difference between the hemoglobin concentration at admission and the hemoglobin concentration on the second postoperative day

was calculated for each patient. Medical charts were reviewed by one of us (M. V.) to establish the presence of postoperative febrile morbidity according to Monif's criteria,[5] document the presence of immediate postoperative morbidity, and estimate the length of postoperative hospitalization.

Statistical differences between the two study groups were assessed by the Student *t* test for means and by the χ^2 or Fisher exact tests for proportions.

Results

Of the 386 patients who had a cesarean section during the study period, 200 were included in the trial. Among the 186 nonparticipants, 43 (23.1%) refused to participate, 41 (22.0%) needed an emergency cesarean section and could not have the protocol explained to them, 91 (48.9%) were not approached because their obstetrician either omitted the explanation (78) or refused to explain the protocol (13), and 11 (5.9%) were excluded because of other miscellaneous reasons. The proportions of repeat cesarean sections and of elective interventions were higher among participants (50.5% and 33.5%, respectively) than the proportions among nonparticipants (25.8% and 25.3%, respectively).

Among the 200 enrolled subjects, 102 were randomized to the standard technique and 98 to the stapling device. Ten subjects had a standard hysterotomy albeit they were allocated to the stapler group. Of these, two belonged to the first 100 enrolled subjects and eight to the second 100 patients. The reasons for protocol deviation were as follows. For two patients, the surgeon forgot about the stapling device and extended the 2 cm hysterotomy with his fingers. In three women, two of whom had a prolonged bleeding time, the stapling device could not be inserted because of substantial bleeding from the small hysterotomy site. Two other patients had a spontaneous uterine dehiscence after the 2 cm scalpel hysterotomy. Three cases were considered technically too difficult (e.g., overweight patient with two previous cesarean sections).

Finally, two patients from the stapler group had a hysterotomy with staples combined with a scalpel or manual extension of hysterotomy. In one of these patients, an inverted "T" incision was needed to deliver a fetus in transverse lie; in the other patient, the obstetrician abandoned the stapler because the stapler insertion on the first side caused a uterine tear and active bleeding.

Patient characteristics in the two study groups. Patients were considered to be in the group to which they had been allocated, whether or not the stapling device was used. Baseline characteristics of the study groups are shown in Table I. Nine obstetricians participated in the study. The distribution of patients according to the obstetrician involved in the procedure was similar in the two groups. Except for a lower proportion of primary cesarean sections in the group with the stapling device, the two groups harbored only small differences with regard to the factors that could influence the study outcomes. Eight patients in the stapling device group (8.2%) and 12 (11.8%) in the standard hysterotomy group had more than one previous cesarean section (χ^2 = 0.37, 1 degree of freedom[df], p = 0.54). All previous incisions were low transverse. Besides tubal ligations, no additional interventions were performed in either group. The proportion of patients who were in labor or had their membranes ruptured before the cesarean section did not differ between the two groups. Among patients in labor, the mean duration of labor was similar in both groups: 9.9 (SEM, 1.2) hours in the stapler group versus 10.1 (SEM, 0.9) hours in the standard technique group (t = 0.10, 55 degrees of free-

†Difference between the hemoglobin at admission and the hemoglobin on the second postoperative day.

dom, $p = 0.92$). The duration of membrane rupture averaged 12.7 (SEM, 1.5) hours for the patients in the stapler group versus 10.4 (SEM, 1.0) hours for the patients with the standard technique ($t = 1.29$, 51 degrees of freedom, $p = 0.20$).

Blood loss and operating time according to the hysterotomy procedure. Subjective assessment by the obstetrician of total blood loss and of blood loss as a result of the hysterotomy led to lower estimates for the group with the Auto Suture Poly CS 57 disposable surgical stapler technique in primary as in repeat cesarean sections (Table II). However, the differences in mean blood loss between the two groups were rather small, varying between 52 and 109 ml according to the measure and the subgroup of subjects considered. Only the difference in the total blood loss between the two study groups reached statistical significance (mean ± SEM, 492 ± 24 vs 579 ± 38 ml, $p = 0.05$). The fall in the hemoglobin concentration from admission to the second postoperative day was very similar in the two groups and did not differ significantly from one group to the other. Only one patient, belonging to the standard group, required a perioperative transfusion.

The mean durations of the operative phases are shown in Table III. The time from uterine incision to closure of hysterotomy was not shortened by the use of the stapling device. Instead, all operative phases tended to be of longer duration with the use of the stapling device as compared with standard procedure. However, the largest difference observed reached only 5 minutes and concerned the total operating time in primary cesarean sections (42 vs 37 minutes, $p = 0.03$).

Exclusion from the stapled group of the 10 subjects for whom the staples were not used did not alter the results presented here.

Technical difficulties related to the use of the stapling device for hysterotomy. In 40 of the 88 patients (45.5%) for whom the Auto Suture Poly CS 57 disposable surgical stapler was used, the surgeons did not use all the staples available. The number of unused staples varied between two and 16 and averaged five. The reasons given for not using all staples were: no hold in the tissues (two subjects), stapler too long (35 subjects), staples not staying closed (two subjects), uterine tear while passing the stapler (one subject).

Accidental extension of the hysterotomy was reported in 37 (42%) patients. Significant bleeding originating from the hysterotomy extensions was observed in 62.2% of these 37 patients. The length of the extension ranged from 1 to 5 cm with an average of 2.9 cm. An extension of the hysterotomy occurred in 31% of the patients for whom all staples were used, whereas it was reported in 55% of those for whom some staples were not used. Accidental extension of the hysterotomy was not less frequent in the second half of the study (45.0%) than in the first (39.6%).

In six of 88 patients, bleeding from the hysterotomy occurred because a uterine vein was accidentally punctured by the retaining pin of the stapler.

No major complication or fetal injury was encountered with the use of the stapling device.

Postoperative febrile morbidity and hospital stay. Four (4.1%) patients from the stapler group and six (5.9%) from the standard hysterotomy group had fe-

brile morbidity according to Monif's criteria (Fisher exact test, $p = 0.75$). In the stapler group, two of these cases of febrile morbidity were attributed to endometritis and two fevers were of unknown origin. In the group with the standard procedure, the fever was attributed to wound infection in two patients, to endometritis in one patient, and was of unknown origin in three subjects. The mean postoperative stay was identical in the two groups (mean ± SEM, 6.3 ± 0.1 days).

Comment

To our knowledge, this is the first randomized trial comparing the Auto Suture Poly CS 57 disposable surgical stapler with the standard procedure in low transverse hysterotomies for cesarean sections. Our results indicate that the operating times, the risk of febrile morbidity, and the postoperative hospital stay are not reduced with the use of the stapling device for this operation. Subjective assessments of blood loss were somewhat lower for patients in the stapler group. However, the differences were small and of questionable clinical significance. Moreover, when objectively estimated by the hemoglobin deficit measured on the second postoperative day, blood loss did not differ according to the hysterotomy technique.

Our results are only partly consistent with those published by Burkett et al.[4] In their retrospective study of 62 cesarean sections with staples and an equal number of cesarean sections without staples, these authors observed, as we did, a longer operating time in the primary cesarean sections with staples than in the nonstapled group. On the other hand, the deficit in hemoglobin reached statistical significance in their study, whereas it did not in ours. But the main difference in the results from the two studies concerns the effect of the stapling device on the risk of endometritis. Burkett et al.[4] reported a significant reduction in the frequency of endometritis from 22.5% in the nonstapled group to 6.4% in the stapled group. They could not provide an explanation neither for this large difference between the two study groups nor for the unusually high frequency of endometritis in their study population. The reduction of endometritis observed with the staples shortened the length of hospital stay and substantially reduced the costs related to the hospitalization in that group. Such benefits were not observed in our study population, in whom the overall endometritis rate was much lower (1.5%).

According to the obstetricians who used the stapler within our study, a traction applied on the lower uterine segment with an Allis forceps while introducing the stapler facilitated the procedure and allowed a more horizontal and thus a longer incision. Furthermore, there is probably room for improvement in the design of the stapling device. In our opinion, the most important complication related to the stapler is the bleeding that sometimes occurs at the site of the retaining pin. This pin is situated at the distal extremity of the stapling device, outside the last staple. Although the retaining pin is important to assure an adequate closure of the staples, its actual location outside the last distal staple is disturbing. If the lower uterine segment happens to be highly vascularized, this pin can puncture a uterine vein and cause substantial bleeding. This explains why the operator in 35 of our study patients considered the stapler "too long" and did not use all the staples available. In those cases, rather than using the whole length of the stapler and risking a uterine vessel puncture by the retaining pin, the operator chose to insert only part of the stapler in the uterus and to clip off the excess staples present at the medial extremity of each hemihysterotomy.

In conclusion, given the cost of the stapling device

and the absence of marked benefits from its use, our study does not support the routine use of the actual Auto Suture Poly CS 57 disposable surgical stapler in low transverse hysterotomies for cesarean sections.

The associated anomalies that determine prognosis in congenital omphaloceles

Marisa Tucci, MD, and Harry Bard, MD

Montreal, Quebec, Canada

Congenital abdominal wall defects such as omphaloceles can be recognized by fetal ultrasonography. To determine whether associated anatomic features may be useful in determining fetal prognosis, a retrospective study was performed over a 5-year period. There were 28 cases of omphalocele; 16 were larger than 5 cm and classified as giant, and the remainder were considered small. Eleven of the 12 infants with small omphaloceles survived with minimal neonatal complications. Ten of the 16 infants with giant omphaloceles died because of associated congenital anomalies. These were congenital heart disease, central nervous system malformations, and diaphragmatic hernias. This review suggests that the prognosis is good when a prenatal diagnosis of giant omphalocele is made and careful fetal ultrasonography, including echocardiography, does not identify heart, central nervous system, or diaphragmatic malformations, even when there is liver herniation into the omphalocele. (AM J OBSTET GYNECOL 1990;163:1646-9.)

Key words: Congenital abdominal wall defects, omphalocele, prenatal diagnosis

The incidence of omphaloceles is reported to be 1 in 4000 to 5000 live births.[1] The current widespread use of prenatal fetal ultrasonography enables the early detection of abdominal wall defects, the most common of which are omphaloceles. It also permits the possible identification of other fetal anomalies frequently associated with this defect.[2] However, for the antenatal findings to be better used in predicting prognosis, it is important to have information on the short-term outcome of these infants, especially those with large omphaloceles. A high incidence of major congenital anomalies has been reported in infants with giant omphaloceles; the prognosis has been considered especially poor when there is liver herniation into the omphalocele.[3-5]

The object of this study was to compare the infants with congenital omphaloceles who survived with those who died. On the basis of the differences found, this could lead to a better identification during prenatal ultrasonography of those fetuses with a good prognosis. This information could be particularly important to obstetricians, pediatric surgeons, and neonatologists.

usually between 16 and 20 weeks' gestation with other ultrasonographic examinations if indicated.

A retrospective analysis of the charts of 28 cases of omphalocele was performed. The elements most specifically sought were size of the omphalocele and its characteristics, associated malformations, and outcome. Cardiac anomalies were diagnosed by echocardiography. The infants were classified in accordance with the University of Colorado intrauterine growth charts.[6] These infants were divided into two groups: those with giant and those with small omphaloceles. Omphaloceles were classified as giant if ≥5 cm in diameter.[4, 5]

Results

A totals of 28 cases of central omphaloceles were reviewed. Among these, 12 were <5 cm and could therefore be labeled as small omphaloceles, whereas 16 were deemed giant because they were ≥5 cm in diameter. There was no significant predominance of either sex.

In the group of 12 infants with small omphaloceles, eight infants were born at term (with one small for gestational age and seven appropriate for gestational age), one was postterm appropriate for gestational age, and three were preterm appropriate for gestational age. Among the three preterm infants, the most premature was born at 29 weeks' gestation; the other two were born at 34 and 35 weeks' gestation. Meckel's diverticulum was noted in four of these infants. Ileal atresia was present in one case. Beckwith-Weidemann syndrome with macroglossia and hypoglycemia was suspected in one infant. One infant had trisomy 21. Only one infant died in this group of 12 with small omphaloceles. This unpreventable death was not related to the presence of an omphalocele. The infant's mother had premature rupture of the membranes at 19 weeks' gestation. The infant was born at 29 weeks' gestation and had evidence of lung hypoplasia. Unfortunately, autopsy was refused by the parents. The other 11 infants in this group with small omphaloceles had no significant problems and had excellent outcomes with no complications.

There were 16 infants in our study who were classified as having giant omphaloceles. In this group 12 were term (nine were appropriate for gestational age and three were small for gestational age), one was postterm appropriate for gestational age, and three were preterm appropriate for gestational age. Among the three preterm infants, the most premature was born at 29 weeks of gestation; the other two were born at 34 and 35 weeks of gestation. Ten of these 16 infants with giant omphaloceles died. Table I lists the major anomalies in these 10 infants. Five had severe congenital heart defects. There were three infants with diaphragmatic hernias and two with central nervous system malformations. One infant died of respiratory complications after abdominal wall closure and had no evidence of other associated malformations.

Among the six infants with giant omphaloceles who survived, none had associated severe malformations. Table II lists the major features found in those who survived. One infant in this group had trisomy 21. Four of the infants in the group of six survivors had evidence of liver herniation into the omphalocele.

Comment

The purpose of this study of omphaloceles was to redefine or confirm the influence of various features on the outcome of affected infants. The size of the defect is a factor known to be of prognostic importance. Previous studies have already ascertained that small omphaloceles are rarely associated with other severe anomalies and have an excellent prognosis. The prognosis of newborn infants with giant omphaloceles is not as good. The outcome in these infants is influenced by several factors, in particular the type of malformations frequently found to be associated with large omphaloceles.[4, 5, 7] All but one of the infants with small omphaloceles survived, whereas fewer than half of the infants with giant omphaloceles survived. Those with giant omphaloceles who died had at least one major congenital anomaly in addition to omphalocele. Those who survived had no other major anomalies.

It is evident that the presence of a giant omphalocele with multiple anomalies is indicative of a poor prognosis. Among the numerous anomalies found in these

infants, one that is particularly indicative of a grave prognosis is the presence of the diaphragmatic hernia. All three infants in our study who had giant omphaloceles and diaphragmatic hernias did not survive. The two organ systems that, when affected, seemed to play a more important role in determining outcome were the brain and heart. All infants with either central nervous system anomalies or major congenital heart defects died.

Studies in the past have suggested that liver herniation is associated with a neonatal death rate as high as 88%.[3,5] It would be logical to state that the presence of liver among the herniated viscera may indeed be an indication of the importance of the defect. In this study, the presence of a herniated liver alone was not of prognostic importance in relation to survival. In fact, on the basis of this small series, a fetus with a giant omphalocele without any other major anomaly, even when the liver is herniated, can have a good prognosis.

Whenever a congenital omphalocele is suspected, targeted prenatal ultrasonographic examination by qualified obstetricians or radiologists to recognize detailed fetal anomalies becomes crucial. With the use of fetal echocardiography, recognition of congenital heart defects is possible and could allow antenatal detection of severe cardiac malformations.[8] A methodical, rigorous use of imaging technology by qualified individuals would permit the identification of those aforementioned features that are indicative of a graver prognosis. Other diagnostic tests such as amniocentesis and fetal blood sampling by cordocentesis may be appropriate. Consequently, realistic expectations can be explained to parents, and a rational management for the further conduct of the pregnancy can be formulated.

In summary, the features identified as having the most influence on the outcome of an infant with an omphalocele were (1) whether the ompalocele was qualified as giant, (2) the existence of multiple associated congenital anomalies (especially central nervous system or congenital heart defects), and (3) the presence of a diaphragmatic hernia. Despite the size of the defect, even when the liver is herniated, the absence of other associated major malformations could be indicative of good prognosis.

Ultrasonographic assessment of placental abnormalities

Eric Jauniaux, MD,* and Stuart Campbell, FRCOG
London, England

Current ultrasonographic techniques offer a novel approach for the identification of a wide variety of placental abnormalities usually described postnatally by the pathologist. Placental vascular lesions, placental tumors, and abnormal placentation are potentially associated with perinatal complications and their diagnosis in utero may influence the pregnancy management. An ultrasonographic classification of placental lesions that is based on their location, size, echogenicity, and number is proposed. Repeated ultrasonographic examination, together with biologic investigations, is important for the prenatal differential diagnosis of most of these lesions and for full understanding of their pathophysiologic characteristics and significance. (AM J OBSTET GYNECOL 1990;163:1650-8.)

Key words: Ultrasonography, placenta, prenatal diagnosis

Recognition of normal and abnormal placental features is a prerequisite for the interpretation of ultrasonographic images. However, despite >20 years of experience in examination of the placenta in utero by ultrasonography, controversies still exist regarding the terminology and the significance of different placental ultrasonographic features.

The purpose of this work is to review the different placental ultrasonographic abnormalities together with their pathophysiologic and clinical implications.

Placental development and maturation

The development of the placenta has always attracted considerable interest from both anatomists and ultrasonographers. Combined studies using transvaginal ultrasonography, hysteroscopy, chorionic villus sampling, and hysterectomy specimens from the first trimester of pregnancy have recently indicated the absence of continuous blood flow in the intervillous space before 12 weeks of gestation.[1-3] During the first trimester of pregnancy, the placenta is bathed by a clear fluid probably composed of maternal plasma and uterine gland secretions.[1-3]. After 12 weeks the trophoblastic plugs in the spiral arteries that are still remaining from the first extravillous trophoblastic wave no longer obliterate the uteroplacental arteries, and a real circulation is then established.[1]

Ultrasonographic evidence of placental textural changes in vivo were reported in early studies during the second and third trimesters.[4-6] A ultrasonographic classification system for grading placentas in utero was developed by Grannum et al.[7] The placental maturational changes were determined by use of a contact B-scanner and graded from 0 to III. These placental changes were correlated with fetal pulmonic maturity evaluated in utero by amniotic fluid lecithin/sphingomyelin (L/S) ratios obtained by amniocentesis. An ideal correlation of 100% was found between placental grade III and mature L/S ratios, suggesting that ultrasonographic placental grading might replace amniocentesis as a standard test to assess fetal pulmonic maturity. Other authors[8, 9] presented similar results using real-time ultrasonography. However, larger studies showed that the sensitivity of the placental grading system as an indicator of pulmonic maturity was poor.[10-14] In addition, this system falsely predicted fetal lung maturity in 8% to 42% of the cases and was therefore not accurate enough to replace amniocentesis for this purpose.[10-14] A modified classification that is based on multiple placental ultrasonographic sections was also proposed, suggesting that placentas should be considered mature only when grade III changes are present in all sections.[15]

Various interpretations of the placental structural changes, interobserver variation in scanning technique, and heterogeneity of the study groups are probably

Table I. Differential diagnosis of principal placental lesions reported in the literature

Location	*Sonographic features*	*Pathologic classification*
Fetal plate	Multiple sonolucent areas limited to the placental periphery (Fig. 1, *A*)	Circumvallate placenta
		Circummarginate placenta
	Single sonolucent or hypoechoic area surrounded by a thin membrane (Fig. 1, *C* and *F*)	Subamniotic cyst
		Old subamniotic hematoma
	Single hyperechoic area surrounded by a thin membrane (Fig. 1, *E*)	Recent subamniotic hematoma
	Well-circumscribed heterogeneous mass protruding into the amniotic cavity (Fig. 2)	Chorioangioma
Placental tissue	Small sonolucent area in the center of the cotyledon	Centrocotyledonary cavity
	Large sonolucent area (Fig. 3, *A*)	Large avillous zone (cavern)
		Septal cyst
		Early stage of thrombosis formation
	Large hyperechoic area (Fig. 3, *C* and *E*)	Old thrombosis
		Infarct
	Multiple sonolucent areas of various sizes and shapes (Fig. 4)	Hydatidiform transformations
Maternal plate	Large hyperechoic area	Recent retroplacental hematoma
	Large sonolucent or hypoechoic area	Old retroplacental hematoma

responsible for the controversies generated by the placental grading system. Nevertheless, all these studies have highlighted that complicated pregnancies have a different maturation pattern than normal pregnancies. This important clinical finding was confirmed by further selective studies. Pregnancies complicated by chronic hypertension or preeclampsia and/or intrauterine growth retardation present an accelerated placental maturation, whereas diabetes and maternal-fetal rhesus incompatibilities are associated with delayed placental maturation.[16] Earlier maturational changes were also described in twin gestations, as compared with singleton gestations,[17] and after exposure to maternal smoking.[18, 19] Pregnant women with mature placental appearance (grade III) on ultrasonography between 34 and 36 weeks' gestation have an increased risk of problems during labor, and their babies have an increased risk of low birth weight, intrapartum distress, and perinatal death.[18] This study also demonstrated that there was a significant decrease in the risk of perinatal death when the grading was known by the clinician responsible for care.[18]

Most of the above-mentioned studies refer to placental senescence or aging to explain the placental maturational changes observed by ultrasonography. Light or electron microscopic study of villi from term placenta does not indicate an aging process.[20] Furthermore, the total placental deoxyribonucleic acid levels continue to rise in a linear fashion until, and beyond, the fortieth week of gestation.[21] Therefore the placental ultrasonographic changes should not be considered as the morphologic hallmarks of placental senescence.

Several authors have attempted to reproduce in vitro the ultrasonographic morphologic features observed in vivo.[4, 5, 22] In early studies the placentas were not always fixed immediately and some changes observed in vivo were not found in vitro; furthermore, new features were probably created during placental collapse.[4, 5] More satisfactory results were obtained with the use of a perfusion system in vitro, to avoid placental collapse.[22] Sonolucent areas or central echo-free spaces have been correlated with avillous zones, and the peripheral echoes with septal calcification and fibrin deposition.[4, 5]

Classification of placental ultrasonographic lesions

Many inaccurate and misleading expressions have been used by sonographers to described placental pathologic lesions. This is probably because of the fact that little attempt has been made to compare ultrasonographic and postpartum findings. The location, the shape, and the echogenicity of the lesion and the number of lesions are the principal ultrasonographic features for the prenatal differential diagnosis of placental abnormalities (Table I).

Placenta extrachorialis. Placenta extrachorialis is characterized by a transition of membranous to villous chorion within the placental disk at a variable distance from the placental edge.[20, 23, 24] Between 18% and 30% of placentas are of the extrachorial variety.[20] Two anatomic entities have been described: circummarginate placentas, which have a flat ring of membranes made up only of amnion and chorion, and circumvallate placentas, which have a raised, often rolled ring of membranes, containing amnion, chorion, and decidual tissue.

Circummarginate placentas are practically asymptomatic.[20] In contrast, circumvallate placentas are associated with a relatively high rate of premature rupture of the membranes, antepartum bleeding, and preterm onset of labor.[20, 23] These complications are

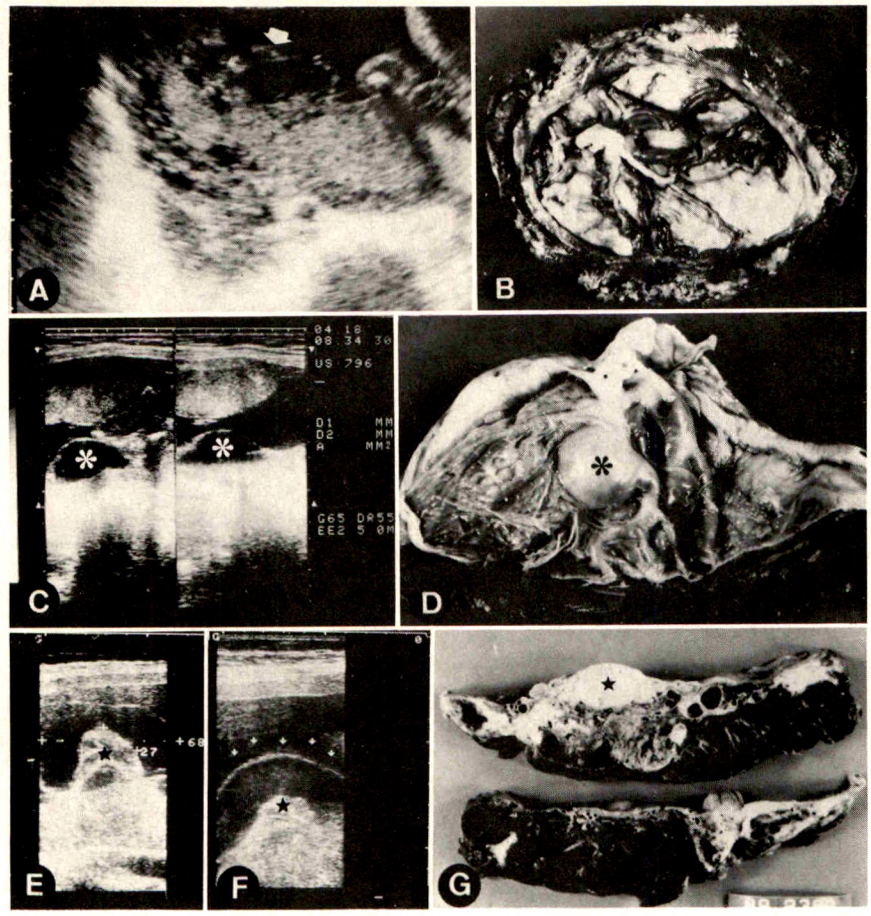

Fig. 1. A, Transverse scan at 20 weeks of gestation of the marginal zone of the placenta, showing sonolucent areas over the fetal plate *(arrow)*. These abnormalities were found only near the placental edge. **B**, Pathologic examination demonstrated a circumvallate placenta. **C**, Transverse and longitudinal scans of a single sonolucent subamniotic area *(asterisk)* at 32 weeks corresponding to a subamniotic cyst (**D**) *(asterisk)*. **E** and **F**, Longitudinal sonograms at 24 and 32 weeks, respectively, showing hyperechogenic placental lesions on the top of the fetal plate *(stars)*, surrounded by a thin membrane *(arrows)*. The lesion becomes less echogenic as the clot resolves. **G,** Pathologic examination revealed an old subamniotic hematoma *(star)*.

probably due to a lack of adaptation of the rigid placental edge with tearing of membranes as the uterine wall stretches in the second half of gestation.

Multiple subamniotic sonolucent areas of various sizes and shapes, located in the periphery of the placenta (Fig. 1, *A* and *B*) are the main ultrasonographic features of this form of placentation.[25]

Cytotrophoblastic cysts. Cytotrophoblastic cysts usually have a single, round or oval cavity, containing a gelatinous material.[20, 23, 24] They can be divided into septal cysts when they are located within the placental tissue and subchorionic cysts when they are on the fetal surface beneath the chorionic vessels.[23, 24]

These cysts are isolated from the placental circulation and appears ultrasonographically as single sonolucent areas (Fig. 1, *C* and *D*) showing no blood flow on real-time imaging.[26] Cytotrophoblastic cysts are found in 20% of placentas at term.[20] Their incidence in increased in pregnancies complicated by diabetes mellitus or maternal-fetal rhesus incompatibility.[20]

Subamniotic hematomas. These lesions are secondary to the rupture of a fetal vessel before or during delivery and are located beneath the amniotic layer covering the fetal plate.[20] Their incidence is unknown but most of them are found in third-trimester placentas and are thought to occur during delivery as a result of excessive traction on the umbilical cord.[20] Subamniotic hematomas that develop during the second or third trimester are sometimes complicated by fetal growth retardation and abnormal Doppler measurements.[27, 28]

Ultrasonographically, they appear as a single mass protruding from the fetal plate and surrounded by a thin membrane. The newly formed clot is echogenic

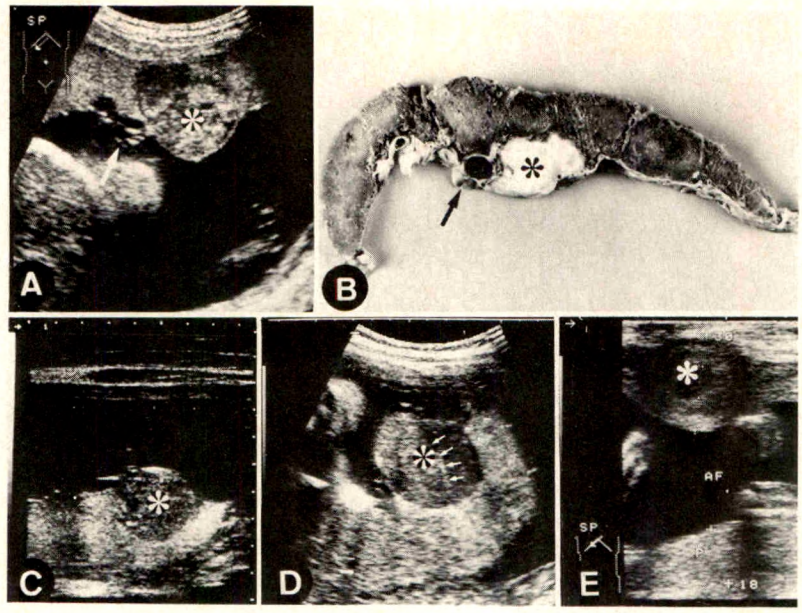

Fig. 2. A, Heterogeneous placental mass at 32 weeks *(asterisk)*, protruding from the fetal plate near the cord insertion *(arrow)*. The pregnancy was complicated by polyhydramnios. **B**, Pathologic examination demonstrated a chorioangioma *(asterisk)* showing generalized degenerative changes. **C**, Longitudinal ultrasonogram of a hypoechoic placental mass *(asterisk)* at 18 weeks gestation. **D**, At 30 weeks half of the lesion *(asterisk)* was more echogenic. At delivery the lesion corresponded to a large chorioangioma partly grooved by bands of fibrous tissue. **E**, Ultrasonographic appearance of a uterine leiomyoma *(asterisk)* at 20 weeks of gestation, for comparison.

(Fig. 1, *E*), but the lesion becomes less so as the clot resolves (Fig. 1, *F* and *G*).

Chorioangiomas. Chorioangiomas occur in 0.5% to 1% of placentas examined at term.[22, 23] Most chorioangiomas are encapsulated, single, small, round, and intraplacental.[20, 23] Large tumors can be of variable shape, divided by fibrous septa, and they often protrude from the fetal surface near the cord insertion.[20, 23] Degenerative changes such as necrosis, calcification, hyalinization, or myxoid changes are frequently present in large tumors. Chorioangiomas are associated with an increased incidence of polyhydramnios and fetal growth retardation.[20, 27] Large tumors (>5 cm in diameter) can also be complicated by fetal cardiac failure with hydrops because of the shunting of blood through the tumor.[20]

On ultrasonographic, only large chorioangiomas protruding into the amniotic cavity have been documented. They are well circumscribed, have a different echogenicity from the rest of the placental tissue (Fig. 2, *A* and *B*), and are easily detectable early in pregnancy by ultrasonographic.[27, 29-31] The echogenicity varies according to the degree of degenerative changes present in the tumor (Fig. 2, *C* and *D*).

Caverns. These lesions may vary from small sonolucent areas to large sonolucent spaces (Fig. 3, *A*). Small echo-free spaces in the center of the cotyledon have been described in normal third-trimester mature placentas (grade III of Grannum's classification). These small cavities within the cotyledons are secondary to the dispersion of the free-floating terminal villi by maternal arterial jets of blood entering the intervillous space.[22]

Larger intraplacental sonolucent spaces are found in 67% of the placentas examined by ultrasonography from the first half of pregnancy until delivery.[32] They contain turbulent blood flow on real-time imaging and their shape can be modified by maternal position or by uterine contractions.[26] Histologically, these lesions correspond to large avillous areas surrounded by normal villi. They are probably a nonpathologic variation of the normal placental anatomic structure that develops from early in pregnancy.[26] They have been described by pathologists as hemorrhagic areas[20] or as caverns,[23] sometimes containing semifluid or fluid blood.

Thrombosis. Placental thrombosis is the result of focal coagulation of blood in the intervillous spaces and usually occurs during the third trimester.[20, 23, 24] Intervillous thromboses are found in about 40% of placentas and contain an admixture of fetal and maternal blood.[20, 24] The incidence of the lesion is increased in pregnancies complicated by rhesus isoimmunization.[20]

Large hypoechoic areas with low flow laterally and relatively high flow in the central part on real-time imaging can be observed in the early stages (Fig. 3, *A*) of the development of an intervillous thrombosis.[26, 32, 33] Abnormal hemodynamic flow in the intervillous space

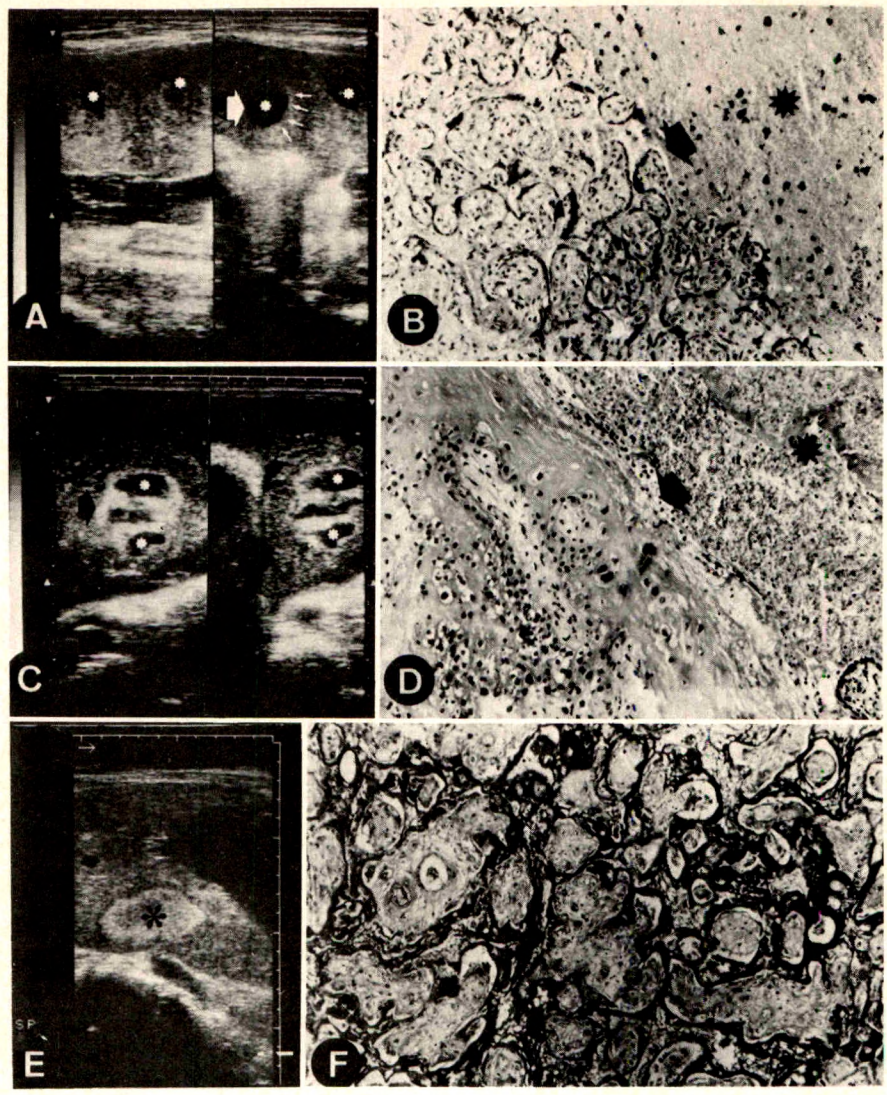

Fig. 3. A, Ultrasonograms at 35 weeks showing small and large placental sonolucent spaces *(asterisks)*, containing turbulent blood flow. Note the increase echogenicity of the surrounding villi *(small arrows)*. **B**, Histologic section at the level of the *large arrow* showing a recent intervillous thrombosis *(asterisk)* and normal villi *(arrow)*. The villi surrounding the lesion at the level of the *small arrows* were compressed and infarcted. (Hematoxylin and eosin. ×50.) **C**, Ultrasonograms at 39 weeks showing a large placental lesion *(asterisk)* corresponding (**D**) to an organized intervillous thrombosis *(asterisk)* with extensive fibrin deposition *(large arrow)* in periphery. (Hematoxylin and eosin. ×50.) **E**, Large placental hyperechoic area *(asterisk)* located near the basal plate at 32 weeks of gestation corresponding (**F**) to a chronic infarct. (Hematoxylin and eosin. ×50.)

may result from the failure of the cotyledon to expand in response to the increasing flow of the corresponding uteroplacental artery and compression of the surrounding villi with gradual atrophy as fibrin accumulates in the periphery. This process causes a progressive increase in the echogenicity of the lesion (Fig. 3, *C* and *D*), thus distinguishing it from a placental cavern. Finally, the maternal blood coagulates in the placental tissue, focally obliterating the intervillous circulation. This failure to accommodate may be secondary to inadequate venous drainage from the cotyledon or to villous damage related to maternal-fetal incompatibility.[20, 23]

Intervillous thrombosis must be distinguished from subchorial thrombosis as a result of pooling and stasis of maternal blood beneath the chorionic plate or in the marginal area of the intervillous chamber.[26, 34] Ultrasonographically, these lesions appear as sonolucent space of variable size containing turbulent blood flow on real-time imaging.[26] Their appearance may change from one examination to another as progressive fibrin deposition leads to classic subchorial or marginal thrombosis described by the pathologists.[20, 23]

Infarcts. Placental infarcts are the result of obstruction of a uteroplacental artery leading to focal degeneration of the overlying villous tissue.[20, 23] They are

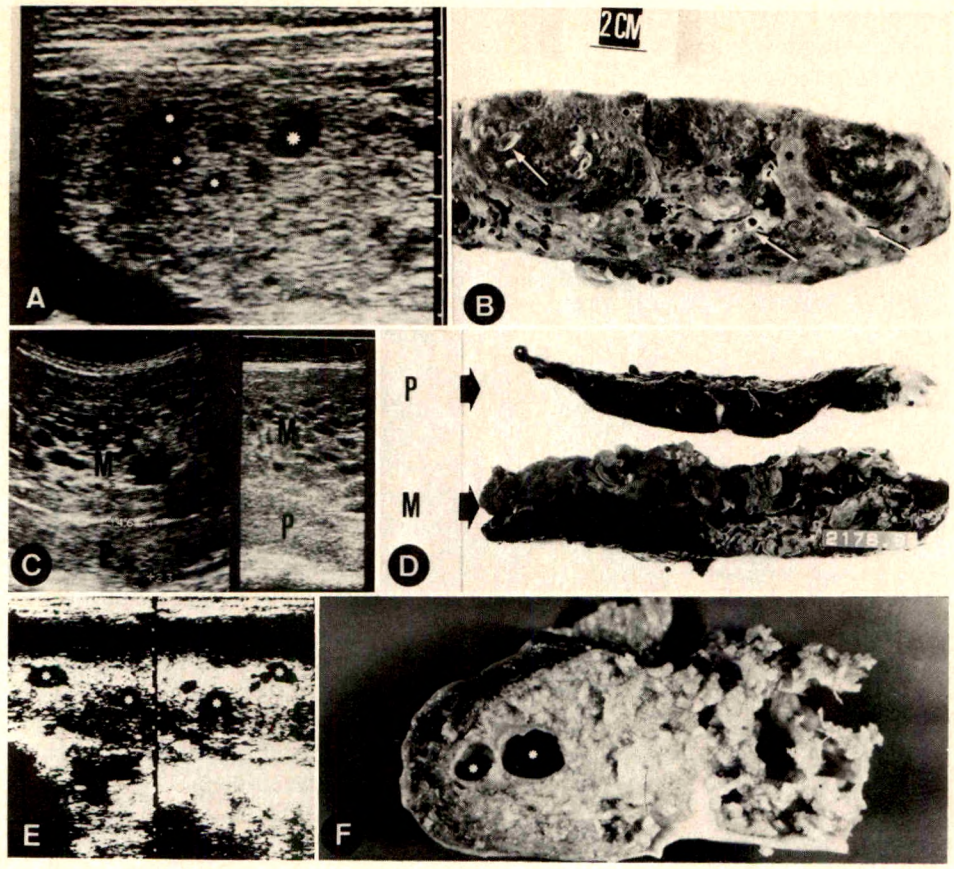

Fig. 4. A, Longitudinal ultrasonogram at 22 weeks of gestation showing an enlarged placenta containing multiple sonolucent spaces *(asterisk)*. The fetus was anatomically normal. **B**, Pathologic examination demonstrated diffuse mesenchymal hyperplasia with myxoid degeneration of the villous stem and dilatation of the main fetal vessels *(arrows)*. **C**, Ultrasonogram at 25 weeks of a molar mass *(M)* and a normal placenta *(P)* in a twin pregnancy combining a classic mole and a normal placenta and fetus. **D**, Pathologic examination confirmed the presence of a normal placenta *(P)* and a complete mole *(M)*. **E**, Transverse ultrasonograms of an enlarged placenta containing multiple sonolucent spaces of various sizes and shapes *(asterisk)*. The pregnancy was complicated by severe asymmetric fetal growth retardation, oligohydramnios, and early pregnancy-induced hypertension. **F**, Pathologic and cytogenetic investigations revealed a triploid syndrome with focal swelling of the villous tissue *(asterisk)*.

usually located near the maternal plate.[20, 23] Small infarcts are found in about 25% of placentas from uncomplicated pregnancies.[20] The incidence of placental infarction is significantly increased in pregnancies complicated by preeclampsia or essential hypertension[20, 23, 24] and is directly related to the severity of the disease.[20, 23] In these maternal hypertensive disorders infarction is extensive and involves more than 10% of the placental tissue.[20] Large placental infarcts are associated with an increase in perinatal mortality and intrauterine growth retardation.[20, 23, 24]

Ultrasonographically, placental infarcts appear as large intraplacental areas that are irregular and hyperechoic in the acute stage[26] and isoechoic in more advanced stages (Fig. 3, *E* and *F*).

Hydatidiform transformation. Molar or hydatidiform transformation of the villous tissue (Fig. 4, *A*, *C*, and *E*) is a common finding in placental trophoblastic tumors. The principal histologic feature of this group of tumors is trophoblastic hyperplasia. Trophoblastic tumors are classified on a cytogenetic and morphologic basis into complete and partial mole.[35, 36]

Complete or classic hydatidiform moles are characterized by generalized swelling of the villous tissue, trophoblastic hyperplasia, and no embryonic or fetal tissue.[35, 36] Complete moles are almost always diploid with a 46,XX chromosomal constitution in 90% of cases and a 46,XY karyotype in 10% of cases.[37] About 15% to 20% of complete moles can become invasive and metastasize.[38] Ultrasonographically, the uterus is filled with sonolucent spaces ("snowstorm" appearance) of various sizes and shapes without embryonic or fetal material.[34] However, molar transformation of one ovum in a dizygotic twin pregnancy has been reported.[39, 40] In these cases ultrasonographic or pathologic examination shows a molar placental mass together with normal placenta and fetus (Figs. 4, *C* and *D*).

Partial hydatidiform moles are characterized by focal

Table II. Review of perinatal features of 35 cases of triploid syndromes diagnosed in second and third trimesters of pregnancy (references 43 to 54)

A. Maternal data (No. = 20)	
Mean maternal age (yr)	25.95 ± 4.91
Mean gravidity	2.1 ± 0.89
Mean parity	0.75 ± 0.83
B. Mean gestational age at diagnosis (wk) (No. = 33)	21.12 ± 4.31
C. Maternal complications (13 cases)	28.6%
6 Pregnancy-induced hypertension	
4 Bilateral multicystic ovaries	
3 Hyperemesis gravidarum	
3 Vaginal bleeding	
D. Ultrasonographic findings	
Placenta (No. = 34)	
Normal in 15 cases	44.1%
Abnormal in 19 cases	55.9%
4 Hydropic (enlarged)	
10 Molar transformations	
5 Hydropic and molar transformations	
Fetus (No. = 33)	
Normal in 3 cases	9.1%
Abnormal in 30 cases	90.9%
18 IUGR	
4 Malformations	
8 IUGR and malformations	
Amniotic fluid (No. = 28)	
Normal in 15 cases	53.6%
Abnormal in 13 cases	46.4%
9 Oligohydramnios	
4 Polyhydramnios	
E. Laboratory findings	
Maternal serum hCG (No. = 10)	
Elevated in 9 cases and normal in 1 case	
Maternal serum AFP (No. = 14)	
Elevated in 13 cases and normal in 1 case	
Amniotic fluid AFP (No. = 15)	
Elevated in 6 cases and normal in 9 cases	
F. Pathologic findings	
Placenta (No. = 31)	
Normal in 12 cases	38.7%
Abnormal in 19 cases	61.3%
9 Molar transformations	
12 Trophoblast hyperplasia and/or scalloped outline	
Fetus (No. = 26)	
Normal in 2 cases	7.7%
Abnormal in 24 cases	92.3%
21 Small for dates	
13 External defects	
10 Internal abnormalities	
G. Cytogenetic findings (No. = 35)	
69,XXX (20 cases)	
69,XXY (13 cases)	
69,XYY (no cases)	
70,XXYY (1 case)	
46,XY/69,XXY (1 case)	

IUGR, Intrauterine growth retardation; *No.*, number of cases among the 35 cases reviewed with the corresponding information; *hCG*, human chorionic gonadotropin; *AFP*, α-fetoprotein.

swelling of the villous tissue, focal trophoblastic hyperplasia, and embryonic or fetal tissue.[35, 36] The most common karyotype found in these cases is triploidy. This is a common chromosomal anomaly accounting for 1% to 2% of all clinically recognized human conceptions.[41, 42] There is a strong correlation between the origin of the extra set of chromosomes, the degree of the placental molar change, and the survival rate of the pregnancies.[42] All cases with an extra paternal set (73%) of chromosomes have significant molar changes (Fig. 4, *E* and *F*) while only 14% of cases with an extra maternal set (27%) have significant molar changes.[42] Placentas with nonmolar changes are associated with a better fetal survival and are more likely to be found near term.[42]

Table II summarizes the perinatal data of 35 cases of triploidy reported in the literature.[43-54] Only triploidy syndromes confirmed by chromosomal analysis were included. This review indicates that 55.8% of the placentas in triploidy have hydropic and/or molar changes on ultrasonography. The fetus presents severe growth retardation and/or major congenital defects in 90.9% of the cases and the amniotic fluid volume is abnormal in 46.4%. The ultrasonographic features correlated well with the morphologic findings reported in these cases and in more selective pathologic studies.[42] This review is not exhaustive and most of these studies are incomplete; in particular, microscopic findings and laboratory investigations were not constantly reported. Nevertheless, published biologic findings indicate that most of the cases of triploidy are first seen with elevated levels of maternal serum human chorionic gonadotropin and α-fetoprotein even when they are not associated with major congenital fetal defects.

Cases of diploid partial moles were recently described. They are characterized by diffuse molar placental changes associated with a normal fetus and elevated levels of human chorionic gonadotropin and α-fetoprotein.[55] Pathologically, areas bearing characteristic molar transformation (diploid cytogenetic constitution) interdigitate with unaffected placental areas.[55, 56]

Molar changes of the placenta are not always pathognomonic of trophoblastic disorders and can be found in other placental pathologic conditions such as benign diffuse mesenchymal hyperplasia (Fig. 4, *A* and *B*) or in prolonged placental retention in utero after fetal death.[26, 57]

Retroplacental hematomas. The diagnosis of abruptio placentae during the second half of pregnancy is based on the clinical triad of pain, uterine rigidity, and vaginal bleeding, and ultrasonographic investigations can be used only in nonacute cases to confirm clinical diagnosis and to exclude presence of placenta previa.[58]

Retroplacental hematomas cause a wide spectrum of ultrasonographic features depending on the location of the lesion and on the degree of organization of the blood clot. Acute hemorrhage is hyperechoic to isoechoic, as compared with placental tissue, while resolving hematomas are hypoechoic.[59]

Other placental abnormalities. Unusual placental abnormalities associated with perinatal complications also have been observed by ultrasonography such as placenta membranacea[60] or placenta percreta.[61]

Comment

Depending on the delay between the development of a lesion in utero and delivery, the ultrasonographic and pathologic findings can be very different. The ultrasonographic features of most placental vascular lesions may undergo major changes within few days. When placental abnormalities that could be associated with perinatal complications are suspected, serial ultrasonographic examinations should be performed.

Repeated ultrasonographic examination will also yield interesting pathophysiologic data on the development of placental lesions and may help in the prenatal differential diagnosis. For example, old thromboses are difficult to differentiate from infarcts if serial examinations are not performed. Repeated ultrasonographic examination is necessary to detect the evolution of a simple hypoechoic space into intervillous thrombosis or to differentiate a subamniotic cyst from a subamniotic hematoma. The increasing echogenicity of a chorioangioma with gestation can be related to fibrotic degeneration of a lesion,[27] which may indicate a reduced risk of high-output fetal cardiac failure.

Placental ultrasonographic examination must be combined with other prenatal investigations, some of which may help in the differential diagnosis. For example, elevated maternal serum levels of human chorionic gonadotropin are suggestive of trophoblastic disorders while elevated α-fetoprotein levels are less specific of a typical placental lesion[27, 62, 63] but indicate a breakdown of the maternal barrier such as may occur in infarcts or thrombosis.

Various vascular lesions have been found in placentas from pregnancies complicated by abnormal fetal or maternal Doppler indices.[64, 65] Although it is unlikely that a clinical decision will be made on placental morphologic features alone, the association of abnormal placental features with abnormal Doppler indices will clarify the hemodynamic changes occurring in these cases. Furthermore, the advent of color Doppler imaging may help to differentiate in utero between maternal and fetal vascular placental abnormalities.

Progesterone increases cardiovascular toxicity to cocaine in nonpregnant ewes

Mark A. Plessinger, MS, and James R. Woods, Jr., MD
Rochester, New York

Cocaine produces a greater hypertensive response in pregnant ewes than in nonpregnant ewes. To determine whether pregnancy-related progesterone levels augmented this cocaine response, six nonpregnant ewes were surgically oophorectomized, implanted with femoral artery and vein catheters, and later administered progesterone 10 mg/kg intramuscularly for 3 days. Consistent responses in blood pressure and heart rate to intravenous norepinephrine 0.4 and 0.6 μg/kg, before and during progesterone treatment, indicated that progesterone did not increase α-adrenergic receptor sensitivity to exogenous norepinephrine. In contrast, intravenous cocaine at either 1.0 or 2.0 mg/kg produced approximately twofold greater increases in blood pressure and threefold greater increases in heart rate during each day of progesterone treatment when compared with responses to the same dose of cocaine before progesterone treatment. These results indicate that progesterone enhances the cardiovascular response to cocaine and does not involve an increase in α-adrenergic receptor sensitivity. (AM J OBSTET GYNECOL 1990;163:1659-64.)

Key words: Hormones, pregnancy, drugs of abuse, sheep, norepinephrine, cocaine

In a recent report we[1] demonstrated that cocaine, when given at the same dose per kilogram, produced a greater hypertensive response in pregnant ewes than in nonpregnant ewes. To explain these findings we hypothesized that pregnancy-related changes in hormonal levels may increase the cardiovascular sensitivity of pregnant ewes to cocaine. Since cocaine blocks the reuptake of catecholamines at nerve terminals, hormonally induced changes in α-adrenergic receptor sensitivity to norepinephrine may account for the increased cocaine sensitivity observed in pregnancy. Therefore the purpose of this study was to examine the heart rate and blood pressure responses to cocaine in oophorectomized nonpregnant ewes before and after treatment with the pregnancy hormone progesterone. Responses to norepinephrine before and during progesterone treatment also were examined to determine the influence of progesterone on α-adrenergic receptor sensitivity.

Material and methods

Six nonpregnant ewes were used in this study. Surgery, care, and use of sheep in this protocol have been approved by the University Committee on Animal Research of the University of Rochester to ensure compliance with the Animal Welfare Act of 1970 and the National Institutes of Health Policy on Laboratory Animals. Before surgery for implantation of catheters, each ewe was sedated with an intravenous injection of 0.02 mg/kg of a 100:1 ketamine hydrochloride/xylazine hydrochloride mixture preceding tracheal intubation. Anesthesia was maintained during surgery with halothane/oxygen by means of an Air-Shield Ventimeter ventilator 2 surgical respirator (Air-Shield, Hatsboro, Pa.). Catheters were placed in the femoral artery for measurement of arterial blood pressure and in the femoral vein for intravenous drug administration. Through a small abdominal incision, each ewe was oophorectomized to prevent hormonal cycling during the experimental period. The catheters were passed subcutaneously along the left flank and placed in a pouch secured to the ewe's side. Initial studies were conducted at least 5 days after surgery to allow for surgical recovery. Catheters were flushed daily with 1000 IU/ml heparin sodium.

Physiologic measurements. In each experiment blood pressure and heart rate were monitored continuously. Blood pressure was monitored by attaching the arterial catheter to a pressure transducer (Micron MP-

15D, Micron Instruments Inc., Los Angeles) that was connected to a pressure amplifier (SensorMedics 9853C, SensorMedics Corp., Anaheim, Calif.). Heart rate was measured by a cardiotachometer (SensorMedics 9857) connected in series with the blood pressure amplifier. Blood pressure and heart rate were continuously recorded on a SensorMedics R-611 eight-channel recorder. Pulse pressure was computed as systolic blood pressure minus diastolic blood pressure.

Doses

Norepinephrine administration. To evaluate α-adrenergic receptor sensitivity, 0.4 and 0.6 μg/kg norepinephrine [(−)arterenol bitartrate salt (Sigma Chemical Company, St. Louis)] in physiologic saline solution (0.9% sodium chloride) was given before and each day of progesterone administration. Norepinephrine 0.4 μg/kg was first administered intravenously as a 2 second bolus injection. At least 60 minutes passed before the 0.6 μg/kg norepinephrine dose was given in a similar manner. An additional 60-minute period elapsed after the 0.6 μg/kg norepinephrine dose before cocaine administration.

Cocaine administration. Doses of cocaine hydrochloride (Sigma) were dissolved in 5 ml of physiologic saline solution. Cocaine was administered intravenously as a 30-second bolus injection in a random fashion at either 1.0 or 2.0 mg/kg body weight. At least 2 hours was allowed to elapse before each animal received the second dose.

Progesterone administration. One to 3 days after the initial responses to norepinephrine and cocaine were obtained, each ewe was injected intramuscularly with progesterone (Eli Lilly & Co., Indianapolis) 10 mg/kg daily for three consecutive days. This dose level, when given to nonpregnant ewes, has been previously shown to produce serum progesterone levels comparable to those of pregnancy.[2] Approximately 2 hours after each progesterone administration, the two doses of norepinephrine and two doses of cocaine were injected as described above.

To determine progesterone levels, a 5 ml blood sample was drawn from the femoral vein catheter each day, approximately 2 hours after progesterone administration but before norepinephrine and cocaine administrations for later analysis of serum progesterone levels. These serum samples were analyzed for progesterone levels by solid-phase iodine 125 radioimmunoassay (Diagnostic Products Corporation, Los Angeles). The lowest level of detectability of this method is 0.05 ng/ml.

Data analysis. For data analysis baseline measurements of heart rate and blood pressure were obtained at 25 and 5 minutes before each respective drug administration and computed as a mean baseline value. Since most of the response activity to norepinephrine and cocaine occurred within the first 2 minutes, response measurements to norepinephrine administration were obtained at 10-second intervals over the first 2 minutes and at 5, 10, 15, and 30 minutes. Response measurements to cocaine were obtained at the same time intervals as the norepinephrine responses with an additional measurement at 60 minutes.

To determine statistical significance, a three-way [factors = dose (2), time (17 or 18), and day of progesterone treatment (4)] repeated measures analysis of variance with a post hoc Newman-Keuls range test was used to determine differences between means when a significant F ratio was obtained by analysis of variance. Statistical significance was established at a p value of <0.05.

Results

Administration of progesterone 10 mg/kg intramuscularly produced serum progesterone levels comparable to those observed during pregnancy in the

sheep.[2] The mean ± SEM progesterone levels in nanograms per milliliter serum were as follows: before progesterone, 0.28 ± 0.05; day 1 treatment, 97.8 ± 40.3; day 2 treatment, 125.3 ± 41.0; day 3 treatment, 119.4 ± 15.4. Baseline measurements of systolic pressure, diastolic pressure, mean arterial pressure, pulse pressure, and heart rate before norepinephrine and before cocaine administration during all 4 days of experimentation (before progesterone and during 3 days of progesterone treatment) demonstrated that progesterone treatment for 3 days had no significant effect on baseline cardiovascular values (Table I).

Norepinephrine produced dose-dependent and significant increases from baseline values in systolic blood pressure, diastolic blood pressure, mean arterial pressure, heart rate, and pulse pressure (Table II). For each dose of norepinephrine the maximum cardiovascular response was constant before and during all 3 days of progesterone treatment (Table II). However, the responses to cocaine demonstrated an approximately twofold greater and significant maximum increase from baseline values in systolic blood pressure, diastolic blood pressure, mean arterial pressure, and pulse pressure (Table III). In response to cocaine, 1.0 mg/kg, heart rate increased approximately threefold when compared with the heart rate response before progesterone was administered. Although a significant difference was not obtained at the 2.0 mg/kg dose, the trend toward increased heart rate response to cocaine after progesterone treatment was maintained (Table III).

The cardiovascular response values to norepinephrine and cocaine were plotted versus time for each of

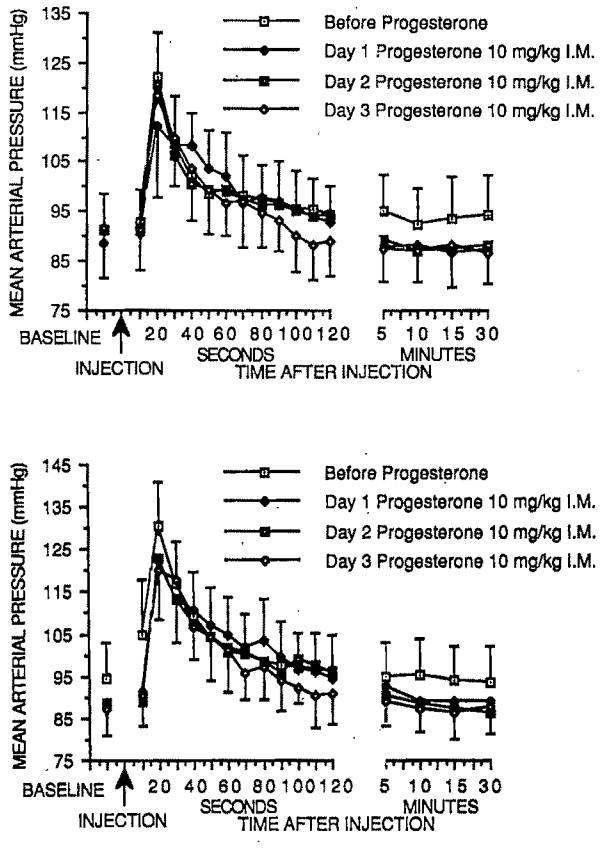

Fig. 1. Responses of mean arterial pressure to intravenous bolus injections of 0.4 μg/kg *(top)* and 0.6 μg/kg *(bottom)* norepinephrine plotted against time. Different *symbols* indicate responses before and during each of 3 days of progesterone treatment, 10 mg/kg intramuscularly. Values represent mean ± SEM from six oophorectomized ewes.

the 4 days of experimentation. For either dose of norepinephrine, the maximum response changes of mean arterial pressure occur at approximately 20 seconds after norepinephrine administration (Fig. 1). As illustrated, the mean arterial pressure responses to norepinephrine were constant over all 4 days of experimentation, indicating that progesterone treatment had no influence on the responses to norepinephrine. It is noteworthy that all responses to either dose of norepinephrine were virtually identical regardless of the day of experimentation or the timing sequence.

In contrast, when the cardiovascular responses to cocaine were plotted versus time, a different response pattern emerged. Cocaine produced its maximum effect on mean arterial pressure at approximately 40 seconds after injection (Fig. 2). Mean response values of mean arterial pressure were significantly increased after progesterone treatment from 40 to 120 seconds after cocaine injection but were equivalent to the response values to cocaine injection before progesterone treatment by 5 minutes and throughout the remainder of the experimental period. These results indicate that progesterone treatment augments the cardiovascular response to cocaine in nonpregnant ewes and that this augmented response occurs within the first 5 minutes after cocaine injection.

Comment

The results of this study indicate that treatment of nonpregnant oophorectomized ewes with the pregnancy hormone progesterone produced an increased cardiovascular responsiveness to intravenous cocaine. Cocaine produced an approximately twofold increase in systolic blood pressure, diastolic blood pressure, mean arterial pressure, and pulse pressure from their respective baseline values after treatment with 10 mg/kg progesterone intramuscularly when compared with the responses measured at the same dose of cocaine before progesterone treatment was initiated. In addition, the heart rate response to cocaine was increased approximately threefold after progesterone treatment. This increased responsiveness to cocaine occurred within hours after administration of the first dose of progesterone and was persistent over all 3 days with little difference between each day of progesterone treatment (Table III, Fig. 2). These results were consistent with our previous observation that pregnant ewes exhibit an increased cardiovascular responsiveness to cocaine when compared with responses from nonpregnant ewes given identical doses in milligrams per kilogram.[1] In addition, the cardiovascular responses of the progesterone-treated nonpregnant ewes to cocaine in the current study closely resemble those responses previously obtained from pregnant ewes.[1,3,4] We have hypothesized that increased sensitivity of pregnant ewes to cocaine may be due to an increased adrenergic receptor sensitivity, a change in cocaine metabolism, or an increased cardiac responsiveness, all of which may be dependent on an alteration in hormonal environment.

Cocaine exerts its pharmacologic action by blocking the uptake of released catecholamines within the synaptic cleft of nerve terminals, prolonging their actions at the effector terminals and increasing their concentrations in the bloodstream.[5] As a result, cocaine produces vasoconstriction by increasing the concentrations of norepinephrine locally in the synaptic cleft and systemically in the peripheral vasculature.

Exogenous norepinephrine was used in this study to determine whether progesterone treatment produced an alteration in α-adrenergic sensitivity. The lack of change in norepinephrine responses after progesterone when compared with the response before progesterone suggests that there is no increase in α-adrenergic receptor sensitivity that could account for the increased hypertension to cocaine observed in the progesterone-

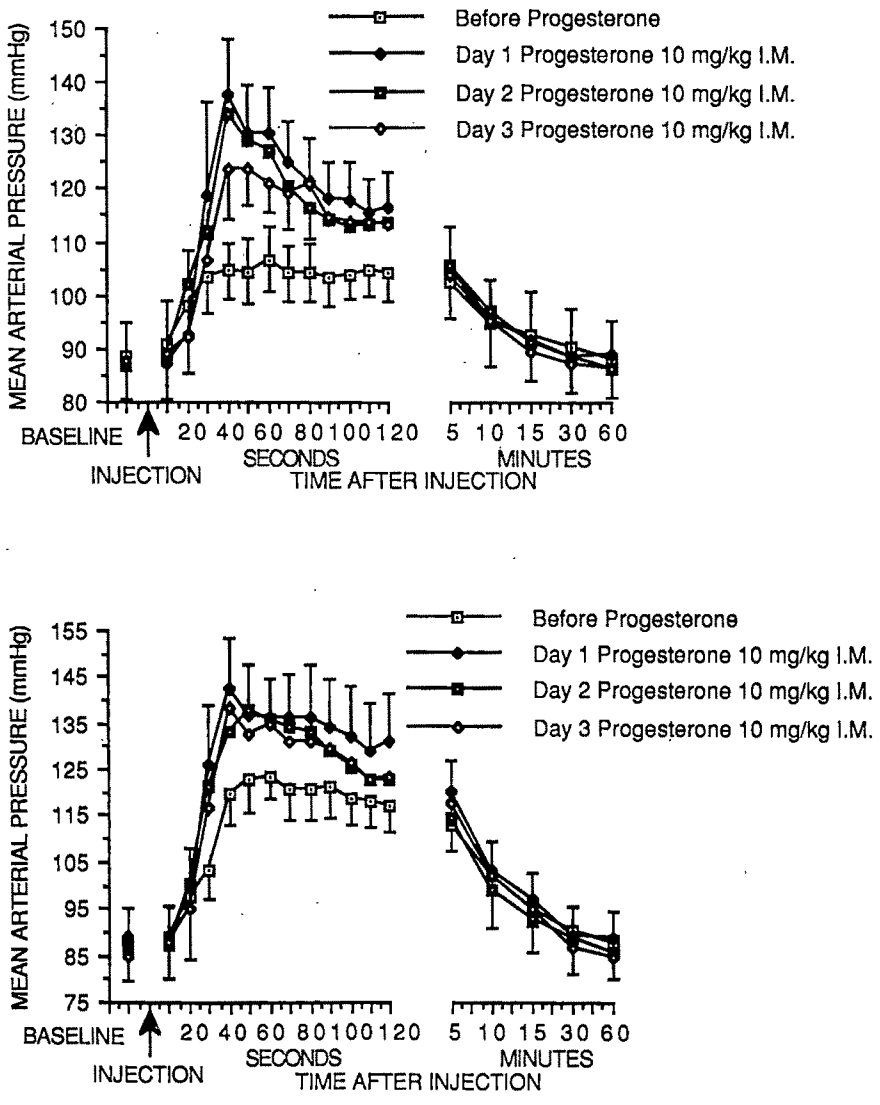

Fig. 2. Responses of mean arterial pressure to intravenous bolus injections of 1.0 mg/kg *(top)* and 2.0 mg/kg *(bottom)* cocaine. Different *symbols* indicate responses before and during each of 3 days of progesterone treatment, 10 mg/kg intramuscularly. Values represent mean ± SEM from six oophorectomized ewes.

treated ewes. Vascular α_1- and α_2-receptor activation by norepinephrine has been demonstrated to produce vasoconstriction and pressor responses in pithed dogs.[6,7] Because of these dual actions of norepinephrine, we cannot determine from our data whether progesterone increases the sensitivity of α_1- or α_2-subsites since norepinephrine is nonselective for these receptors. Progesterone could sensitize vascular α_1-receptors while desensitizing vascular α_2-receptors with the net effect producing no change in the pressor response to norepinephrine. Of note, the peak blood pressure responses to either dose of norepinephrine were higher before progesterone than after progesterone treatment (Fig. 1). If the progesterone-treated nonpregnant ewe is similar to the pregnant ewe in its cardiovascular sensitivity to norepinephrine, this trend is in keeping with observations by McLaughlin et al.[8] that the blood pressure response of pregnant ewes to intravenous norepinephrine is less than that of nonpregnant ewes.[8]

The increased cardiovascular responsiveness to cocaine after progesterone administration could be explained by an alteration in cocaine metabolism either as a decrease in the turnover rate of cocaine to its metabolic products or an increased turnover to bioactive metabolic products. Norcocaine is a reactive product of cocaine metabolism and is converted at a rate of 20% of the cocaine dose by *N*-demethylation.[9] Norcocaine is a potent vasoconstrictive agent that inhibits the reuptake of norepinephrine to a greater degree than cocaine.[10] The remaining cocaine and norcocaine

are metabolized by plasma and liver esterases and microsomal monooxygenases.[11] Reports in pregnant rats and rabbits have indicated a decrease in liver cytochrome P_{450} concentrations (−25%), as well as decreased specific activity of glucuronyl transferase[12] and monooxygenase[13] when compared with nonpregnant animals. Ochs et al.[14] demonstrated that progesterone treatment of nonpregnant rats increased the *N*-demethylation of aminopyrine, which has similar kinetics when compared with the *N*-demethylation of cocaine to norcocaine.[15] The progesterone treatment could alter the liver cytochrome P_{450} enzymes, glucuronyl transferases, and monooxygenases to decrease turnover of cocaine and/or increase the *N*-demethylation of cocaine to norcocaine. These changes in enzyme characteristics could produce a delay in the metabolism of cocaine or increase its conversion to norcocaine, explaining the increased responsiveness of the progesterone-treated nonpregnant ewes.

Progesterone could produce an increased cardiac responsiveness to cocaine. In the isolated heart muscle model, hydrocortisone treatment has been shown to increase the force of cardiac muscle contraction to cocaine.[16] This increase in cardiac contractility to cocaine, in the presence of this steroid in vitro, may explain the increased sensitivity of the progesterone-treated ewes by leading to an increased cardiac output and hypertension. The greater increase in systolic blood pressure and widened pulse pressure to cocaine seen after progesterone treatment may therefore reflect an increased cardiac contractility. Although cardiac output was not measured in the current study, cocaine may exert its drug action directly on the heart, producing a greater cardiac output after progesterone treatment. With heart rate used as a relative index of cardiac output, this is a reasonable conclusion since the heart rate response to cocaine was increased after progesterone treatment.

In summary, this study demonstrates that the pregnancy hormone progesterone increases cardiovascular sensitivity to cocaine when administered to nonpregnant ewes. This evidence explains in part the increased cardiovascular sensitivity to cocaine that we have previously observed in pregnant ewes when compared with nonpregnant ewes. Although the mechanism of increased sensitivity to cocaine in pregnant ewes is not clear, it appears to be at least partially related to a unique drug interaction between cocaine and progesterone. Since progesterone demonstrates an increase in cardiovascular sensitivity to cocaine, pregnant women or persons receiving progesterone supplementation may be at increased risk of cardiovascular complications during cocaine use.

Preferential mitogenic activity for myoblast-like cells can be extracted from uterine leiomyoma tissues

Michael Koutsilieris, MD, PhD, Josée Michaud, BSc, and Andreas Nikolis, BSc
Quebec, Quebec, Canada

The presence of mitogen(s) in leiomyoma extracts stimulating cells with the fibroblast, myoblast, and osteoblast phenotype was documented. Mitogenic activity in leiomyoma extracts was acid stable and sensitive to tryptic digestion. Reverse-phase high-performance liquid chromatography successfully separated mitogen(s) with preferential activity for myoblast cells from mitogens with a broad type of cell specificity and from inhibitors. This leiomyoma-derived preferential activity for myoblasts was absent in identically treated myometrial and endometrial extracts. This suggests that leiomyoma-derived substances with preferential growth factor activity for myoblast-like cells may play a role in the pathophysiologic characteristics of uterine leiomyomas. (Am J Obstet Gynecol 1990;163:1665-70.)

Key words: Growth substances, leiomyoma, inhibitors

Uterine leiomyomas are the most common tumors in adult women and one of the most common causes of infertility.[1] The use of electrophoretic types of X-linked enzyme glucose-6-phosphate dehydrogenase has indicated a unicellular histogenesis for leiomyomas.[2] Since fibrous tissue exhibited glucose-6-phosphate dehydrogenase heterogeneity, it was concluded that fibrous tissue within leiomyomas should originate from the same cells or cell clone from which muscle cells originate.[3] Recently a nuclear phosphoprotein (MyoDl) whose expression is restricted to proliferating myoblasts and differentiated myotubes was able to activate a myogenic program in fibroblasts, thus converting fibroblasts to myoblasts.[4] A short region of MyoDl complementary deoxyribonucleic acid (residues 143 to 162) was found to be similar to a conserved region in the c-*myc* family of proteins. Deletion of this region eliminated the capacity of the MyoDl protein to initiate myogenesis.[4] MyoDl phosphoprotein was able to initiate myogenesis in fibroblasts and, interestingly enough, in nonmesodermal cell lines.[4] This was suggestive of its role in explaining the unicellular origin of fibroblasts and myoblasts in uterine leiomyomas as previously reported.[3] The tendency of leiomyomas to develop and grow during the subject's reproductive life and to regress postmenopausally has implicated estrogens as a factor in their pathogenesis. This observation led to the hypothesis that women bearing such tumors would have either an increased serum level of estrogens or an increased concentration of estrogen receptors in the tumor. Since neither of these assumptions has been substantiated,[5-7] progestins, the biologic antagonists of estrogens, were implicated in the pathogenesis of leiomyomas.[8, 9] However, no conclusive data have been obtained.[8-12]

Recent reports have demonstrated differences between enzymatic activity of leiomyoma tissues and that of normal myometrium.[13, 14] Additionally human leiomyomas were found to contain significantly higher cytochrome P_{450} activity than adjacent normal myometrium.[15] Recently, changes in receptors for estradiol, progesterone, and epidermal growth factor in uterine fibromas were reported after treatment with luteinizing hormone–releasing hormone analogs.[16] In addition, the presence of luteinizing hormone–releasing hormone specific binding sites in uterine leiomyomas suggested a direct action of luteinizing hormone–releasing hormone analogs on this tissue.[17]

Previously we have reported the capacity of crude uterine extracts to stimulate cells with the osteoblast and fibroblast phenotype.[18] This suggested that uterine-derived growth substances may play a role in uterine pathophysiologic characteristics.[18, 19] This study characterizes certain uterine mitogens and inhibitors that act on myoblasts, fibroblasts, and osteoblasts. These substances were acid stable and tryptic sensitive. They could be retained and could be eluted from cartridges of C18 silica. Reverse-phase high-performance liquid chromatography (r-HPLC) identified, among various

mitogens with broad-cell-type specificity, preferential mitogen(s) for myoblast-like cells in leiomyoma extracts. This mitogen(s) was absent from myometrial and endometrial extracts that were identically processed. These data suggest that inhibitory and proliferative substance(s) of leiomyoma extracts could formulate the humoral basis of the pathogenesis of uterine leiomyomas.

Material and methods

Tissue specimens were obtained during surgery on young, otherwise healthy women (aged 30 to 38; $N = 10$) who were diagnosed as having uterine leiomyomas and had not received any therapy. These patients had not received oral contraceptives during the last 6 months. Tissues were washed with Hanks balanced salt solution, pH 7.4, and kept frozen at −70° C. Representative tissue specimens underwent routine pathologic examination, and tissues from women in the proliferative ($n = 6$) and secretory ($n = 4$) phases were used in our studies. Tissue was first homogenized at 4° C in acetone (30 ml/gm). The insoluble precipitate was then homogenized in *n*-hexane (30 ml/gm), and the insoluble material from this procedure was homogenized again in acetone (30 ml/gm). The dried and defatted residue was then extracted individually in a mixture of 40 ml/gm of 1 mol/L hydrochloric acid containing 5% (vol/vol) formic acid, 1% (wt/vol) sodium chloride, and 1% (vol/vol) trifluoroacetic acid. This high acid content was to ensure that all peptidases were inhibited. Formic acid and sodium chloride ensured a high yield by minimizing binding of peptides to structural proteins.[18] This acidic extraction medium was designed to maximize solubilization of peptides while precipitating high-molecular-weight proteins. The protein concentration of the extracts was measured by the protein assay of Lowry et al.[20]

Fetal rat calvarial foreskin cells were used to assess the proliferative effects of leiomyoma extracts on fibroblasts.[18] Calvarial foreskins were incubated for 90 minutes at pH 7.4 in Hanks balanced salt solution containing 2 mg of crude collagenase per milliliter; 140 to 160 U/mg (Sigma Chemical Co., St. Louis). Cells released in Hanks balanced salt solution were grown in primary culture with RPMI 1640 medium (Gibco, Grand Island, N.Y.) containing 0% to 10% fetal calf serum (Gibco), depending on the experiment. The American Type Culture Collection mouse myoblast-like cell line (CRL-1456-G8) and the American Type Culture Collection rat smooth muscle embryonic thoracic aorta cell line (CRL-1476-A10) were used to assess the proliferative effect of leiomyoma extracts on myoblasts. The osteoblast-derived osteosarcoma cell line (UMR 106) was used to assess the proliferative effect of leiomyoma extracts on osteoblasts.[18, 19]

Cell lines were maintained in Dulbecco's modified medium F12 containing 10% fetal calf serum in 75 cm culture flasks. Cells were removed from the flasks with a mixture of 0.1% trypsin (Sigma) and 0.01% ethylenediaminetetraacetic acid (Sigma) in Hanks balanced salt solution and were precipitated with low-speed centrifugation. Cells were counted in a hematocytometer with trypan blue exclusion used to assess viability. Then cells were plated at 1.5×10^5 in 24-multiwell plates with Dulbecco's medium containing 0.5% fetal calf serum. Tissue culture was performed at 37° C in an atmosphere of 5% carbon dioxide and 95% air.[19]

To assess stimulation of deoxyribonucleic acid synthesis, samples of leiomyoma extracts or growth factor were added to cultures 48 hours after plating. Cultures were incubated with extracts for 22 hours and sequentially after 2 μCi of tritiated thymidine (specific activity 50 to 80 Ci/nmol; New England Nuclear, Boston) was added to each well. After 2 hours of incubation, the medium was aspirated and the cells were washed twice with ice-cold Hanks balanced salt solution and once with 1 ml of cold 1.2N perchloroacetic acid. The perchloroacetic acid–insoluble material was dissolved in 2 ml of 0.6N sodium hydroxide and tritiated radioactivity was measured by liquid scintillation spectrometry (counting efficiency = 50% to 60%).

The effects of fibroblast growth factor, epidermal growth factor, and insulin (all obtained from Sigma) on tritiated thymidine incorporation were assessed in all indicator cell culture systems.

Mitogenic activity of leiomyoma extracts (200 ng/ml; total protein concentration) was assessed before and after tryptic digestion with ×50 (wt/wt) crude trypsin (Sigma) at 22° C for 24 hours. Reaction was stopped by addition of aprotinin (Boehringer-Mannheim) (aprotinin/trypsin ratio = 15).

Samples of the leiomyoma extracts were first fractionated on cartridges of C18 Silica (Sep-Pak; Waters Associates, Milford, Mass.). Eluates from Sep-Pak testing by 80% acetonitrile containing 0.1% trifluoroacetic acid were lyophilized and then diluted by 0.1% trifluoroacetic acid and chromatographed on high-performance liquid chromatography. High-performance liquid chromatography was performed on a Pharmacia high-performance liquid chromatography system (Piscataway, N.J.) consisting of two LKB 2150 high-performance liquid chromatography pumps, one LKB 2152-020 controller, one LKB 2141 variable wavelength monitor, one LKB 2221 integrator, and one LKB 2212 Helirac fraction collector. Reverse-phase high-performance liquid chromatography was performed on a SuperPac Spherisord ODS2 No. 2134-256 LKB column. Linear gradients of acetonitrile containing 0.1% trifluoroacetic acid as a counter ion were performed over 60 minutes at a flow rate of 1.5 ml/min. Aliquots of the fraction eluted by reverse-

Each value expresses the mean and standard error of triplicate determinations.

phase high-performance liquid chromatography were tested for mitogenic activity on fibroblasts, myoblasts, and osteoblasts.

Results

Crude leiomyoma extracts were capable of stimulating tritiated thymidine incorporation into the deoxyribonucleic acid of cells with the fibroblast, myoblast, and osteoblast phenotype. The effect was dose-dependent (Table I).

Assessment of mitogenic activity of leiomyoma extracts before and after tryptic digestion of a given protein concentration (20 ng/ml) revealed a decrease in the activity of the trypsinized extracts by approximately 70% to 90% (Table II).

The response of our indicator cell cultures to fibroblast growth factor, epidermal growth factor, and insulin was documented. The effects of known growth factors on tritiated thymidine incorporation were dose-dependent (Table III). This indicated that cells could

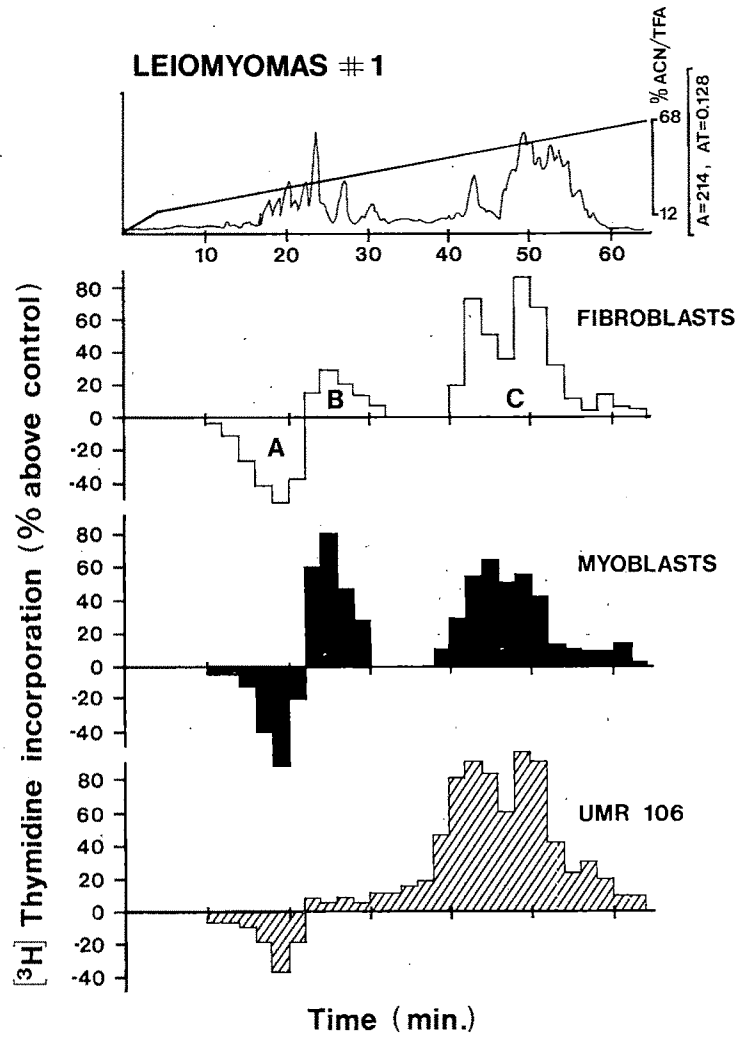

Fig. 1. An example of the ultraviolet profile of leiomyoma extracts (3.2 mg total protein concentration by assay of Lowry et al.[20]) fractionated on reverse-phase high-performance liquid chromatography column (LKB, SuperPac Spherisord ODS 2). Reverse-phase high-performance liquid chromatography was performed on an LKB system monitored for ultraviolet absorbance (-) and bioactivity in assays measuring tritiated thymidine incorporation into cellular deoxyribonucleic acid of fibroblast (□), myoblast (■), and osteoblast (▨) cells. Mitogenic activity was expressed as in footnote to Table I. The columns were eluted with linear gradients of acetonitrile *(ACN)* containing 0.1% trifluoroacetic acid *(TFA)*. Region *A* represents fractions exerting inhibitory activity for all cell types. Region *B* represents fraction with preferential mitogenic activity on myoblast cells. Region *C* represents fractions of reverse-phase high-performance liquid chromatography with mitogenic activity for all cell types.

respond to known mitogens. The response was of similar magnitude to that of leiomyoma extracts.

Reverse-phase high-performance liquid chromatography of leiomyoma extracts (n = 7; proliferative = 4; secretory = 3) revealed mitogenic activity in all three indicator cells (Fig. 1, region C). However, in one region, mitogenic activity specifically stimulated myoblasts, stimulated fibroblasts to a lesser degree, and had no effect on osteoblasts (Fig. 1, region B). This preferential mitogenic activity was detected in all tissue extracts but one (proliferative phase). In addition, one region with inhibitory activity for all three indicator cells was detected (Fig. 1, region A).

Reverse-phase high-performance liquid chromatography of extracts of myometrial (n = 11) and endometrial (n = 4) tissues, although processed identically and chromatographed under identical conditions, failed to reveal region(s) with preferential activity for myoblast cells (data not shown).

Comment

Although the effects of estrogens and progestins on the growth of uterine leiomyomas in vivo are unquestionable, the assumption that these hormones or their receptors are directly responsible for the development of the disease has not yet been substantiated. Also the

mechanism by which these hormones affect tumor growth is undetermined.[6-12]

Assessment of the mitotic activity in uterine leiomyomas revealed that the highest mitotic counts occurred during the early phase of the menstrual cycle, indicating indirectly that leiomyomal growth is affected by progesterone levels. In contrast, the number of and/or the regulation of cytoplasmic progesterone receptors present in normal tissue did not prove to be significantly different from that present in leiomyoma tissues.[8-12] Interestingly, cytoplasmic estradiol and progesterone receptor binding sites in leiomyoma tissues did not change during the menstrual cycle as they did in normal myometrium.[7]

Very recently, the presence of growth factors in normal uterine tissues was documented.[18] This growth substance(s) could stimulate (1) tritiated thymidine incorporation into cellular deoxyribonucleic acid and (2) cell number of cultures with the fibroblast and osteoblast phenotype. This effect was dose-dependent, and the presence or absence of fetal bovine serum in cell culture media did not alter the cellular response.[18, 19]

We extended this investigation to uterine leiomyoma extracts using the primary culture of fetal rat foreskin fibroblasts[18] and cells expressing the myoblast and osteoblast phenotypes as indicator cell systems.[19] The presence of mitogen(s) in crude leiomyoma extracts was steadly documented (Table I). A remarkable stimulation of tritiated thymidine incorporation in a dose-dependent manner similar to the one achieved by fibroblast growth factor, epidermal growth factor, and insulin was achieved (Tables I and III). The concentration range of insulin necessary to stimulate fibroblasts, myoblasts, and osteoblasts was indicative of an effect mediated by insulin-like growth factor type I receptors. The protein nature of mitogen(s) in leiomyoma extracts was evident since a remarkable decrease of the mitogenic activity was detected after tryptic digestion (Table II). In addition, the acid-stable character of this substance(s) was verified because mitogenic activity was extracted in a milieu of pH <2 (see extraction methods). These data suggested that fractionation of leiomyoma extracts with Sep-Pak cartridges of C18 silica was possible. Indeed mitogenic activity of leiomyoma extracts was retained and could be eluted by 80% acetonitrile over 0.1% trifluoroacetic acid from Sep-Pak cartridges (data not shown). These data lead us to the conclusion that reverse-phase high-performance liquid chromatography could be used for purification. Eluates from reverse-phase high-performance liquid chromatography were capable of stimulating tritiated thymidine incorporation into fibroblast, myoblast, and osteoblast-like cells (Fig. 1). Interestingly, one region with inhibitory activity for all indicator cells and another with preferential activity for cells with the myoblast phenotype were detected (Fig. 1). The above was a stable finding in all leiomyoma extracts tested except one. The region of preferential mitogenic activity for myoblasts was absent from all myometrial ($n = 11$) and endometrial ($n = 4$) extracts processed from adjacent uterine tissues and fractionated identically by reverse-phase high-performance liquid chromatography (data not shown).

The presence of mitogen(s) in leiomyoma extracts for fibroblast, myoblast, and osteoblast was expected although not reported previously elsewhere. Previous studies[18, 19] have detected similar mitogens in extracts from human uterine tissues. The presence of different growth factors such as fibroblast growth factor, epidermal growth factor, platelet-derived growth factor, and insulin-like growth factor type I in uterine extracts from different animals has been reported previously.[16] The presence of several growth substances in various normal and/or malignant tissue extracts is now also well documented. For all these growth substances different physiologic and pathologic roles have been assigned.[16, 19] In our opinion the most interesting finding of this study is the presence of preferential mitogenic activity for myoblasts extracted from leiomyoma tissues. The characterization and purification of such preferential mitogens deserves further attention. We believe that this growth substance(s) could be implicated in the pathophysiologic features of uterine leiomyomas and could mediate the action of estrogens and/or progestins on this tissue.

We thank our colleagues of the Departments of Obstetrics-Gynecology and Pathology of our hospital, namely, Drs. J. Belhumeur, J. Bergeron, J. Blanchet, J.-L. Dubé, J.-Y. Fontaine, C. Huot, R. Maheux, G. Quesnel, and M. Marois, for valuable support throughout the study.

Platelet activating factor enhances in vitro fertilization of rabbit oocytes

William E. Roudebush, PhD, Brijinder S. Minhas, PhD, Deborah D. Ricker, MS, Thomas V. Palmer, BS, and Melvin G. Dodson, MD, PhD

Johnson City, Tennessee

Capacitation of spermatozoa is essential for fertilization. Rabbit spermatozoa are particularly difficult to capacitate in vitro and require treatment with high-ionic-strength Brackett's defined medium. Spermatozoa treated with platelet activating factor had significantly higher fertilization rates when compared with nontreated (fresh, twice washed) spermatozoa (63% vs 34%). Fertilization rates of spermatozoa treated with platelet activating factor, although higher than those of high-ionic-strength capacitated spermatozoa, were not significantly different (63% vs 57%). Spermatozoa treated with lyso–platelet activating factor, the biologically inactive form of platelet activating factor, were noted to have fertilization rates similar to those of the untreated (noncapacitated) group. These data show that synthetic platelet activating factor treatment of uncapacitated spermatozoa induces fertilization of rabbit oocytes in vitro in a manner similar to that for spermatozoa capacitated by high-ionic-strength media and significantly higher than that for untreated spermatozoa or after treatment with the biologically inactive form of platelet activating factor (lyso–platelet activating factor). (AM J OBSTET GYNECOL 1990;163:1670-3.)

Platelet activating factor (PAF) [1-0-alkyl-2-0-acetyl-*sn*-glycero-3-phosphocholine] is a potent phospholipid produced by many cell types including macrophages, neutrophils, and platelets and induces a variety of biologic and pharmacologic responses such as platelet aggregation, anaphylaxis, and vascular permeability.[1,2] PAF has also been reported to play a significant role in

reproduction.[3] Human and mouse preimplantation embryos produce and secrete PAF into culture medium in vitro,[4, 5] and embryo-derived PAF is associated with mild thrombocytopenia in early pregnancy.[6, 7] Furthermore, this initial maternal response of platelet activation occurred only in the presence of fertilized zygotes in mice. This mild thrombocytopenia was not observed during pseudopregnancy, in mice that have had tubal ligation and were mated to fertile male mice, or on the transfer of unfertilized eggs; these observations suggest PAF to be of embryonic origin. PAF administration to estrous mice and rabbits results in the appearance of early pregnancy factor in serum.[8, 9] PAF has been detected in rabbit and human ejaculated spermatozoa.[10, 11] However, PAF activity is not found in the seminal fluid.[11] PAF antagonists have been reported to exert spermicidal activity[12] both in vitro and in vivo after vaginal instillation. Synthetic PAF has been shown to have a stimulatory effect on human spermatozoa motility, and enhancement of the penetration rates of zona-free hamster oocytes with PAF-treated sperm has recently been reported.[13-15]

This study reports the effect of synthetic PAF on the in vitro fertilizing capability of rabbit spermatozoa. Fertilization rates of PAF-treated spermatozoa are compared with untreated (noncapacitated) fresh (twice-washed) spermatozoa, spermatozoa capacitated by exposure to high-ionic-strength Brackett's defined medium[16] and spermatozoa treated with a biologically inactive form of PAF (lyso-PAF).

Material and methods

Twenty-four New Zealand White rabbit does (3 to 4 kg) were primed with follicle-stimulating hormone (0.5 mg twice a day for 3 days; Schering, Kenilworth, N.J.) and human chorionic gonadotropin (hCG) (100 IU 12 hours after final dose of follicle-stimulating hormone; Sigma, St. Louis). Oocyte-cumulus complexes were collected 14 hours after hCG administration by flushing the oviducts with Ham's F-10 (Sigma) and treated with hyaluronidase (450 units/ml; Sigma) to remove cumulus cells. Three does did not respond to the simulation protocol. From 21 does, we obtained 407 oocytes (19.4 oocytes per doe), 391 of which were deemed to be morphologically normal. Mature oocytes were pooled, washed twice, and cultured in Brackett's defined medium[16] (300 mOsm/kg) until insemination.

Semen was collected from mature New Zealand White bucks ($n = 2$) (4 to 6 kg) by use of an artificial vagina and diluted with Brackett's defined medium to a final volume of 8.0 ml. Spermatozoa were washed twice by centrifugation (400 *g* for 5 minutes) in Brackett's defined medium and separated into control (fresh, twice-washed) and treatment groups (2 ml of spermatozoa suspension per treatment group). Spermatozoa in the three treatment groups were exposed for 15 minutes to (1) high-ionic-strength Brackett's defined medium (385 mOsm/kg) or (2) PAF (1×10^{-7} mol/L) (Bachem Bioscience, Philadelphia), or (3) lyso-PAF (1×10^{-7} mol/L) (Bachem Bioscience). PAF and lyso-PAF were stored in a stock solution of chloroform and methanol (1:4) before dehydration under a stream of nitrogen and rehydrated with Brackett's defined medium to the final concentration (1×10^{-7} mol/L) used. After the 15-minute exposure, each spermatozoa treatment group was washed twice (400 gm, 5 minutes) with 2.0 ml of Brackett's defined medium and immediately used for insemination. The mature (first polar body) oocytes were inseminated with 1×10^6 motile, fresh, high-ionic-strength Brackett's defined medium, PAF, or lyso-PAF–treated spermatozoa and cultured in Brackett's defined medium in an atmosphere of 5% carbon dioxide in air, 95% relative humidity at 39° C.

After 4 hours of coincubation, the oocytes were washed twice and cultured in Ham's F-10 medium (0.3% bovine serum albumin). Inseminated oocytes were examined for second polar body extrusion and/or formation of pronuclei 12 hours after insemination. The penetrated oocytes were cultured for another 12 hours for assessment of two-cell formation. Fertilization rates are reported as the number of oocytes that proceeded to the two-cell stage of development 24 hours after insemination.

Data were evaluated by a 2×2 χ^2 contingency table.

Table I. In vitro fertilization rates of cumulus-free ovulatory rabbit oocytes

Spermatozoa treatment	*No. of oocytes inseminated*	*Fertilization rate (2-cell formation)*
Control (fresh, washed twice)	101	35 (34.7%)*†
High-ionic-strength Brackett's defined medium	91	52 (57.1%)*
PAF	95	60 (63.2%)†‡
Lyso-PAF	104	45 (43.3%)‡

*$p < 0.01$.
†$p < 0.001$.
‡$p < 0.01$.

Results

PAF treatment of spermatozoa for 15 minutes resulted in a significant increase in the in vitro fertilization rate (63.2%, $p < 0.001$), compared with control untreated spermatozoa (34.7%) (see Table I). Capacitation of spermatozoa with high-ionic-strength treatment also resulted in significantly increased fertilization rates compared with controls (57.1% vs 34.7%, $p < 0.01$).

Fertilization rates with lyso-PAF (biologically inactive

PAF) were similar to the control rates and were significantly ($p < 0.01$) lower than the fertilization rates of the PAF-treated spermatozoa.

Comment

Freshly ejaculated spermatozoa must undergo a period of maturation in the female reproductive tract (capacitation) before they are capable of fertilizing an oocyte.[17] Soon after deposition in the female reproductive tract, spermatozoa undergo a filteration-like process by which they are separated from the seminal fluids, which contain capacitation inhibiting factors.[18] Using immunologic techniques, Oliphant and Brackett[19] demonstrated that in the rabbit system capacitation involves removal of seminal plasma components that coat the spermatozoal surface. Treatment of ejaculated rabbit spermatozoa with high-ionic-strength Brackett's defined medium capacitates rabbit spermatozoa in vitro and enhances the in vitro fertilization of oocytes, possibly by removing the plasma components coating the spermatozoa surface.[16]

In this study we noted the fertilization rates of cumulus-free rabbit oocytes to be similar with spermatozoa treated with PAF or high-ionic-strength Brackett's defined medium. PAF-treated spermatozoa fertilized significantly higher numbers of oocytes than twice-washed (control) and lyso-PAF–treated spermatozoa, indicating that PAF, by some yet unknown mechanism, induces the fertilizing capacity of spermatozoa, presumably by capacitation.

High-ionic-strength treatment of rabbit spermatozoa in our study has yielded fertilization rates of cumulus-free oocytes similar to those for in vivo capacitated spermatozoa.[20] PAF treatment of spermatozoa appears to capacitate rabbit spermatozoa as effectively as both the in vitro (high-ionic-strength Brackett's defined medium) and in vivo capacitation protocols.

The treatment of rabbit spermatozoa with CV3988, a PAF antagonist, before the artificial insemination of does has been reported to significantly decrease in vivo fertilization rates.[12] We have previously reported reductions in the in vitro fertilization rates of mouse oocytes in the presence of CV3988.[21] Furthermore, PAF treatment of mouse spermatozoa also has been shown to enhance in vitro fertilization rates of mouse oocytes.[22, 23]

Reduction of in vivo fertilization of rabbit oocytes on treatment of spermatozoa with PAF antagonists,[12] the presence of PAF in spermatozoa,[10] and enhancement of oocyte in vitro fertilization with treatment of spermatozoa with synthetic PAF are strong indicators of an important role for PAF in fertilization.

Previous reports from our laboratory have documented the presence of PAF in human spermatozoa,[11] stimulation of human spermatozoa motility,[13] and enhancement of in vitro fertilizability of mouse oocytes in the presence of PAF.[22] These data suggest a potential therapeutic use of PAF in promoting fertilization in vitro.

Further studies will be needed to evaluate the use of PAF in human fertilization in vitro and the potential therapeutic value for the treatment of male factor infertility and/or fertilization failure.

Adhesion formation after ovarian wound repair in New Zealand white rabbits: A comparison of ovarian microsurgical closure with ovarian nonclosure

Anne K. Wiskind, MD, Andrew A. Toledo, MD, A. Gatewood Dudley, MD, and Kathryn Zusmanis, BS

Atlanta, Georgia

Thirty female New Zealand white rabbits underwent standard laparotomy. Each ovary was bivalved and hemostasis was achieved with bipolar electrocautery. One ovary was then randomized to the closure group, whereas the other ovary was placed in the nonclosure group. In the closure group, the ovarian capsule was closed with a continuous suture of 8-0 Vicryl absorbable surgical suture material with microsurgical technique. In the nonclosure group, the ovaries were left open. Three weeks later the animals were killed and the ovarian adhesions were graded with a standardized scale by an observer (A. A. T.) blinded to the closure status of the animals. Five control animals underwent sham operations with minimal adhesion formation. Statistical analysis of the study animals by the paired Student *t* test showed a significantly higher adhesion score on the ovaries that were microsurgically closed compared with the ovaries not closed ($p = 0.02$). (Am J Obstet Gynecol 1990;163:1674-8.)

Key words: Ovarian wound, nonclosure, adhesion formation

Postoperative adhesion formation is one of the most unfortunate sequelae of gynecologic surgery and results in mechanical infertility, pelvic pain, and bowel obstruction. Adhesion formation after reconstructive ovarian surgery is particularly frustrating because it may have an important impact on future fertility. Adhesions coating the ovary may interfere with ovulation mechanics and distort tuboovarian relationships, thereby disrupting ovum transport.[1]

Many of the studies that have evaluated both the pathophysiology of adhesions and methods to deter their formation have involved the adhesiogenesis of peritoneal defects with relatively little attention focused on the ovary. However, procedures resulting in ovarian surgical wounds are commonly encountered in women of reproductive age who are then most likely to be adversely affected by the subsequent adhesions. Examples of such procedures include ovarian cystectomy, resection of endometriosis, wedge resection because of polycystic ovarian disease, and rarely, resection of an ovarian pregnancy.

The least adhesiogenic method of managing ovarian surgical defects remains to be determined. Previous studies showed that microsurgical closure with fine synthetic suture is superior to macrosurgical closure with chromic catgut suture.[2] Another study[3] showed that bipolar electrocautery of ovarian surgical defects is less adhesiogenic than macrosurgical closure. However, bipolar electrocautery of ovaries alone has been shown to cause significant adhesions.[3, 4] Thus far there has been no study that compares adhesion formation after ovarian closure using microsurgical technique with ovarian nonclosure. This was the purpose of our study.

Material and methods

The study was approved by the Institutional Animal Care and Use Committee of Emory University, PROTOCOL 125-89, and the animals were housed at Emory University under the supervision of university veterinary staff.

Thirty female New Zealand white rabbits of reproductive age that weighed 2500 to 4300 gm were anesthetized with ketamine hydrochloride 40 mg/kg and xylazine hydrochloride 10 mg/kg body weight. The abdomen was shaved and prepared with povidone-iodine solution, and the animal was draped with sterile sheets for abdominal surgery. Talc was carefully removed from the surgeon's gloves. The animals then underwent laparotomy through a midline abdominal incision approximately 4 to 5 cm long beginning just inferior to the umbilicus. The bowels were carefully packed in the upper abdomen with a moistened lap sponge and a pediatric Balfour retractor. With an op-

erating microscope (model 1402, J.C. Hoppl Corp., distributed by Edward Weck Co., Research Triangle Park), the ovaries were each bivalved longitudinally to the level of the hilum with a No. 15 blade scalpel. Hemostasis of the ovary was achieved with bipolar electrocautery provided by a surgical cautery unit (Micro 120, Aspen Labs, Inc., Littleton, Colo.) on setting five.

Once this was completed on both ovaries, a card was pulled from a sealed envelope and one ovary was assigned to the closure group and the other ovary was assigned to the nonclosure group. In the closure group, the ovarian capsule was closed with a continuous, nonlocking suture of 8-0 Vicryl absorbable surgical suture material (Ethicon, Somerville, N.J.) on a V130-S tapercut needle. Care was taken to include just the ovarian capsule with minimal cortex in each bite of suture. The rabbit ovarian surface was quite friable, requiring that some cortex be included to achieve a smooth closure. The suture bites were no more than 1 mm in depth and were spaced about 1 mm apart for approximately seven to nine bites per ovary. In the nonclosure group the ovary was left open. The randomization of closure and nonclosure was equally distributed between the right and left ovaries.

Careful attention to meticulous microsurgical technique including gentle tissue handling, excellent hemostasis, and continuous irrigation with sterile saline solution was performed throughout the procedure. The Balfour retractor and laparotomy sponge were removed, the abdominal wall was closed with a continuous suture of 3-0 Vicryl absorbable surgical suture material, and the skin was closed with a subcuticular stitch of 4-0 Prolene sutures (Ethicon, Somerville, N.J.) reinforced by simple interrupted sutures of 4-0 Prolene. Descriptions of all operative procedures and notes of special problems were kept in a laboratory diary.

Five control animals also underwent laparotomy in the same fashion with visualization, mobilization, and handling of the ovaries with microforceps, but ovarian incisions, electrocautery, or sutures were not used.

All animals were allowed to recover routinely. Three weeks after the surgery, the animals were killed with a thiopental preparation (Pentothal) 60 mg/kg body weight administered intravenously. A second laparotomy was performed by an investigator blinded to the group status (A. A. T.) who had not been involved in any of the initial surgeries, and the pelvic adhesions were graded by a method suggested by Michael P. Diamond, MD (personal communication). A score of 0 to 1.0 was given for the percentage of ovarian surface involved with adhesions. Separate scores were given to the incision line, the lateral ovarian surface, and the medial ovarian surface, which were then added for a total adhesion score for each ovary (Table I, Fig. 1). Standard analysis of the data was performed with the paired Student *t* test.

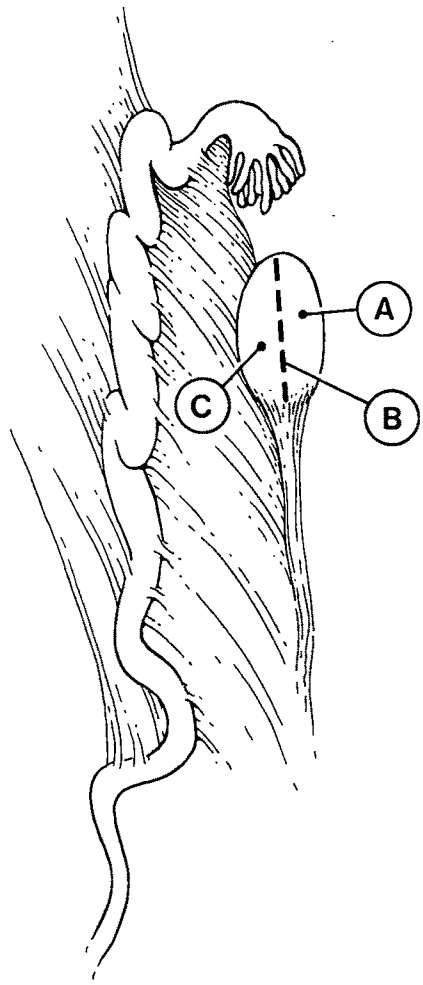

Fig. 1. Ovarian adhesion scale. *A*, Represents medial surface of rabbit ovary; *B*, incision line, and *C*, lateral surface. Percentage of each of these surfaces involved with adhesions is scored individually, then added for total adhesion score for ovary.

Table I. Adhesion score scale

Description of ovary	*Potential score*
Percentage of incision covered with adhesions	0-1.00
Percentage of lateral ovarian surface covered with adhesions	0-1.00
Percentage of medial ovarian surface covered by adhesions	0-1.00
Total adhesion score for each ovary	0-3.00

(Diamond MP. Unpublished data.)

Results

For statistical analysis the animals were divided into two groups: group A (ovarian microsurgical closure) and group B (ovarian nonclosure). Comparison of total

adhesion scores in group A (closure) and group B (nonclosure), summarized in Table II, shows a higher mean adhesion score in group A than that in group B, which is statistically significant to a p value of 0.02.

The five control animals were evaluated separately with no adhesion formation in three animals and minimal adhesions in the other two, suggesting that opening and closing the peritoneum alone contributed little to adhesion formation (Table III). There were also 14 ovaries (23%) in the study animals with an adhesion score of zero. Eight of these were in the nonclosure group, whereas six were in the closure group. Four animals (13%) had no adhesions on either ovary. Graphic plotting of the ovarian adhesion scores from each animal (Fig. 2) shows the higher adhesion scores in the ovarian closure group, with the exception of five animals in which ovarian nonclosure resulted in more adhesions that that of ovarian closure. After reviewing these cases it was found that in one animal the adhesions in both ovaries were minimal; however, the ovary that was closed underwent severe atrophy with subsequently fewer adhesions being formed than in the opposite normal-sized ovary that was not closed. One of the nonclosure ovaries in another animal was fixed deep in the pelvic sidewall. The mobilization necessary to position the ovary for bivalving and bipolar cautery was very difficult and traumatic. In fact, the ovary was separated into three pieces during the procedure, eliciting severe postoperative adhesion formation. In the remaining three animals, there was nothing unusual about the operations to indicate why nonclosure was more adhesiogenic than ovarian closure. It was the opinion of the statistician that these animals should be included in the study group, inasmuch as five of 30 were too many to exclude as outlying data points from a statistical standpoint. Furthermore, it was not considered statistically sound to exclude only one from this group even though excessive trauma was noted.

Marked atrophy was an interesting finding at second laparotomy in eight ovaries. These were evenly distributed among ovaries that were closed and those that were not closed. It was suspected to have occurred as a result of excessive bipolar cautery compromising the ovarian blood supply. However, it was also noted in cases in which only minimal cautery was used. The depth of the hilar incision was kept fairly consistent, but may be indirectly related to ovarian atrophy, inasmuch as the deeper the incision the more cautery required to achieve hemostasis.

In this study 11 ovaries were found encased in dense bowel adhesions. All but one of these ovaries had undergone microsurgical closure. The remaining ovary encased in dense adhesions was not closed, but had been mutilated by excessive trauma during the operative procedure.

Four animals had superficial wound separations. There was no evidence of postoperative evisceration or peritonitis in any of the animals, and they responded to treatment of local wound care. The operating time was approximately 1 hour for most animals, with the exception of the control animals that had an operating time of about 30 minutes.

Comment

In this study we showed that nonclosure of ovarian surgical defects is less adhesiogenic than microsurgical closure in the rabbit model. Most of the adhesions in the closure group involved the incision line; with 100% of the incision line involved in one third of the closed ovaries, and >50% of the incision line was involved in over half these ovaries. All but one case of bowel adhesions to the adnexa involved ovaries in the closure group. In contrast, the incision line was much less frequently involved in adhesions in the nonclosure ovaries. This is consistent with previous studies that showed suture to elicit a foreign body tissue reaction with subsequent adhesiogenesis.[5-7] The paucity of adhesions to the incision line in the nonclosure ovaries suggests that the cauterized ovarian parenchyma did not elicit a significant inflammatory response.

Trauma to tissue during the operative procedure also appeared to be a significant adhesiogenic factor. Most of these adhesions in the nonclosure ovaries involved the lateral and medial surfaces of the ovary and were most likely a result of trauma to the ovarian surface during manipulation. Instances in which excessive trauma to the tissue was noted during the operative procedure resulted in extensive postoperative adhesion formation. In fact, a partial explanation for the greater adhesions scores in the closure group may be the increased amount of manipulation required for surgical closure. Thus gentle, atraumatic tissue handling is of paramount importance in decreasing adhesion formation.[1, 7-10]

Preservation of the ovarian blood supply also is critical to ensure satisfactory results after ovarian reconstructive surgery. Compromise of the blood supply can result from certain types of surgical closure[5, 8] and from excessive electrocautery, as we suspect may have occurred in some of our animals with ovarian atrophy. Failure to preserve a functioning ovary negates the purpose of conservative ovarian surgery.

In applying this study in the rabbit model to the human patient, several factors must be considered. First, the rabbit ovary is much smaller and more friable than that in human beings, measuring approximately 0.8 × 0.5 × 0.3 cm, making subcapsular closure technically difficult, if not impossible, even with the operating microscope. A subcapsular closure that is possible on human ovaries may be less adhesiogenic than the

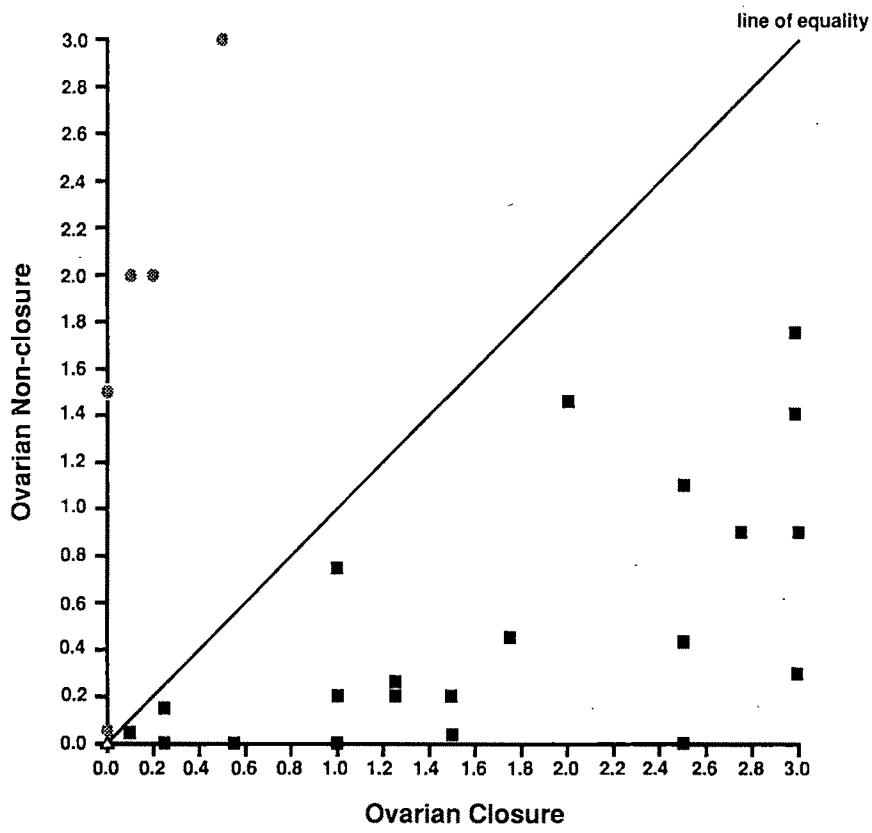

Fig. 2. Graphic representation of adhesion scores for each study animal. Δ Represents four animals with adhesion score of zero on both ovaries. ■ Represents 21 animals with adhesion score of microsurgically closed ovary greater than adhesion score of nonclosure ovaries. ● Illustrates five animals with nonclosure ovary adhesion score greater than adhesion score of ovary microsurgically closed.

continuous suture through the ovarian capsule used in this study.[5] Furthermore, after the surgical defects were created in the rabbit ovaries, the two halves of the ovaries naturally fell together, restoring their natural shape and appearance. In contrast, after many ovarian procedures in human beings, especially after resection of a cyst or an endometrioma, the remaining ovary is often a markedly distorted, thin, elongated shell. Whether adequate blood perfusion, hormone production, and tuboovarian relationships can be reestablished by this distorted ovary is yet to be determined.

In conclusion, our data show that ovarian microsurgical closure is significantly more adhesiogenic than ovarian nonclosure ($p = 0.02$). On the basis of these results, we suggest that for smaller surgical defects in which the ovarian architecture is not significantly altered, nonclosure of the defect is the management of choice. In larger defects in which the ovary is markedly distorted with a large denuded surface, the most appropriate management is unclear. At this time we recommend surgical reconstruction of the ovary by internal closure with a fine synthetic suture. With this technique the edges of the ovarian capsule can be reapproximated and left open. An additional layer of suture to close the ovarian surface is not only unnecessary, but more adhesiogenic. Special emphasis should be placed on atraumatic tissue handling to further minimize adhesion formation.

Effects of danazol, gonadotropin-releasing hormone agonist, and a combination of danazol and gonadotropin-releasing hormone agonist on experimental endometriosis

Masahiro Sakata, MD,[a] Naoki Terakawa, MD,[a] Takahiro Mizutani, MD,[a] Osamu Tanizawa, MD,[a] Keishi Matsumoto, MD,[b] Nobuyuki Terada, MD,[c] and Katsuichi Sudo, PhD[d]

Osaka, Japan

Effects of danazol, gonadotropin-releasing hormone agonist (leuprolide), and danazol-leuprolide combination on experimental endometriosis were evaluated in female rats. A complete resorption of the fluid and a marked decrease in the volume of endometrium autotransplanted under the renal capsule were found after castration (1.4 ± 0.1 mm^3 in castrated, $n = 14$, vs 26.7 ± 5.6 mm^3 in intact control, $n = 16$). Histologic examination indicated atrophy and regression of the endometrial explant. These atrophic changes of endometrial explant were also induced by danazol, leuprolide, and the combination treatment. However, the volume of explants after combination therapy with danazol and leuprolide (1.8 ± 1.0 mm^3, $n = 17$) was significantly less than that after therapy with danazol (11.6 ± 2.8 mm^3, $n = 20$) or leuprolide alone (5.9 ± 1.4 mm^3, $n = 24$). The combination therapy (16/17) was also shown to be superior to danazol (9/20) or leuprolide alone (14/24) to induce the regression of fluid in experimental endometriosis. As expected, administration of leuprolide decreased the serum estradiol level, but use of danazol did not. These findings suggest that a combination therapy of danazol and gonadotropin-releasing hormone agonist, which show different modes of action, may be a potential modality in treatment of patients with advanced endometriosis. (Am J Obstet Gynecol 1990;163:1679-84.)

Key words: Endometriosis, danazol, gonadotropin-releasing hormone agonist, combination therapy

Endometriosis is the presence of functioning endometrial glands and stroma outside the uterine cavity. The prominent symptoms of the disease are chronic pelvic pain and infertility, which are significant problems in gynecology. The disease affects approximately 10% of all women of reproductive age, and the need for an effective nonsurgical treatment is pressing, particularly for patients concerned about their future fertility. Until recently, hormonal therapy of endometriosis has been dominated by use of danazol, an isoxazol derivative of 17α-ethinyltestosterone. The results of several studies have shown the efficacy of danazol in the treatment of endometriosis.[1] Dramatic improvement was noted in terms of both symptoms and signs and laparoscopic findings. The uncorrected fertility rate ranged between 41% and 50%. However, recurrences were common after completion of the treatment and the rates were more than 33% of treated patients.

The chronic administration of potent agonistic analogs of gonadotropin-releasing hormone (GnRH) suppresses gonadal steroid production. Recently GnRH agonist has been used as a form of hormonal treatment for sex steroid–dependent diseases such as endometriosis. In fact, the clinical usefulness of GnRH agonists in the treatment of endometriosis was demonstrated.[2] On the basis of the result of a multicenter double-blind comparative clinical study,[3] both danazol and GnRH agonist nafarelin therapy remarkably reduced the extent of disease as assessed by laparoscopy, and there were no statistically significant differences in the improvement of laparoscopic scores between the two regimens. Of the patients who attempted pregnancy, 39% succeeded after the completion of treatment; similar rates of pregnancy were obtained by both treatments. These results demonstrate that GnRH agonist is as effective as danazol in the treatment of endometriosis. However, a clinical study[3] also showed that the treatment with either danazol or GnRH agonist resulted in a complete resolution in only a few patients with advanced stages. Therefore the establishment of more

6/1/23592

effective hormonal therapy in the treatment of patients with advanced endometriosis is necessary.

The most probable mechanism of action of GnRH agonist–induced resorption of endometriosis is estrogen deprivation and subsequent atrophy.[2-4] Conversely, the mode of action of danazol on the disease is not fully understood. It has been suggested that the action of danazol on endometriosis is attributable to the suppression of ovarian function, caused by either its antigonadotropic nature or inhibition of ovarian steroidogenic enzymes.[1] However, the pharmacologic action of danazol seems to be complex. During danazol treatment serum concentration of sex hormone–binding globulin was markedly suppressed, which resulted in a significant elevation of free testosterone.[5] Danazol also binds to multiple classes of steroid receptors and behaves as an androgen, glucocorticoid, or progestin.[1] A clinical study demonstrated that danazol binds to progestin receptors and shows progestin activity in human endometrium, suggesting a local progestin activity of the drug.[6] Furthermore, a short-term treatment with danazol induced atrophic change in the endometrium without a decrease in the level of serum estradiol.[7] An inhibitory effect of danazol on the growth of human endometrial cells[8] and endometrial adenocarcinoma cells[9] in culture was also demonstrated. These results suggest that danazol acts directly on the endometriotic tissues, and the action mechanism of danazol on endometriosis is different from that of GnRH agonist. A combined therapy with danazol and GnRH agonist may obtain a greater response rate than danazol or GnRH agonist alone in the treatment of patients with endometriosis. Therefore we initiated a trial of experimental endometriosis in female rats to determine whether a combined treatment with danazol and GnRH agonist is superior to danazol or GnRH agonist alone. In addition, possible mechanisms of action of these compounds in endometriosis are discussed.

Material and methods

Study design. To evaluate the effects of compounds precisely, experimental endometriosis was induced in 9-week-old Sprague-Dawley female rats by autotransplantation of endometrium under the renal capsule. After laparotomy the left uterine horn was resected and was opened by longitudinal incision, and the endometrium was dissected from the myometrium. Then a 5 × 5 mm section of endometrium was grafted under the capsule of left kidney of the same animal. Two weeks later the attachment and the viability of endometrial explant were examined by second laparotomy, and the size (length, width, and height) of the explant was measured and the volume was then calculated. The criterion for determination of a viable graft was fluid accumulation. The rate of induction of endometriosis was found to be >80%. The animals with endometriosis (with weights of approximately 250 gm) were randomly divided into five groups: intact rats treated with (1) vehicle alone (intact control), (2) GnRH agonist leuprolide depot formulation (1 mg/kg body weight), (3) danazol (100 mg/kg body weight), (4) or danazol-leuprolide combination, and (5) ovariectomized rats treated with vehicle alone. Daily administration of danazol or vehicle was given by gastric gavage for 3 weeks. Leuprolide depot (leuprolide) was injected once subcutaneously.

In the preliminary study the doses of two agents in female rats (1 mg/kg body weight for leuprolide and 100 mg/kg body weight for danazol) were found to be optimal because the serum concentrations of leuprolide and danazol measured after treatment for 3 weeks were in the same range of those obtained in the clinical use. At third laparotomy performed 3 weeks after the beginning of treatment (24 hours after the last administration of danazol or vehicle), the effects of the treatments on endometriosis were evaluated. The presence of fluid accumulation and the size of endometrial explant were examined. Then the explant was excised and fixed in 10% formalin for histologic evaluation. The ovaries, uterus, and pituitary gland were removed and weighed. Pituitary glands were immediately stored at −80° C for GnRH binding assay. Blood was drawn from the descending aorta, centrifuged, and serum was stored at −20° C for hormone assays. The guidelines for the care and use of the animals in this study were approved by Osaka University Medical School.

Hormone assays. Serum concentrations of luteinizing hormone, follicle-stimulating hormone, and estradiol were measured by radioimmunoassay as described previously.[10] The minimum detectable level of assay was 5 pg/tube for NIADDK-rLH RP-2,* 20 pg/tube for NIADDK-rFSH RP-2,* or 3 pg/tube for estradiol. The intraassay coefficients of variation in these assays were 8.5% for luteinizing hormone, 9.0% for follicle-stimulating hormone, and 8.0% for estradiol. Serum concentrations of danazol and leuprolide were also determined with high-performance liquid chromatography and radioimmunoassay as reported previously.[10, 11] These assays were performed by courtesy of the Division of Research and Development, Tokyo Tanabe Co., Ltd. (Tokyo), and Central Research Division, Takeda Chemical Industries, Ltd. (Osaka). The assay sensitivity was 3 ng/ml for danazol and 5 pg/tube for leuprolide.

GnRH receptor assays. Iodination of GnRH agonist leuprolide and measurement of pituitary GnRH receptors were performed as reported previously[12] unless specified otherwise. Estimation of GnRH receptors was

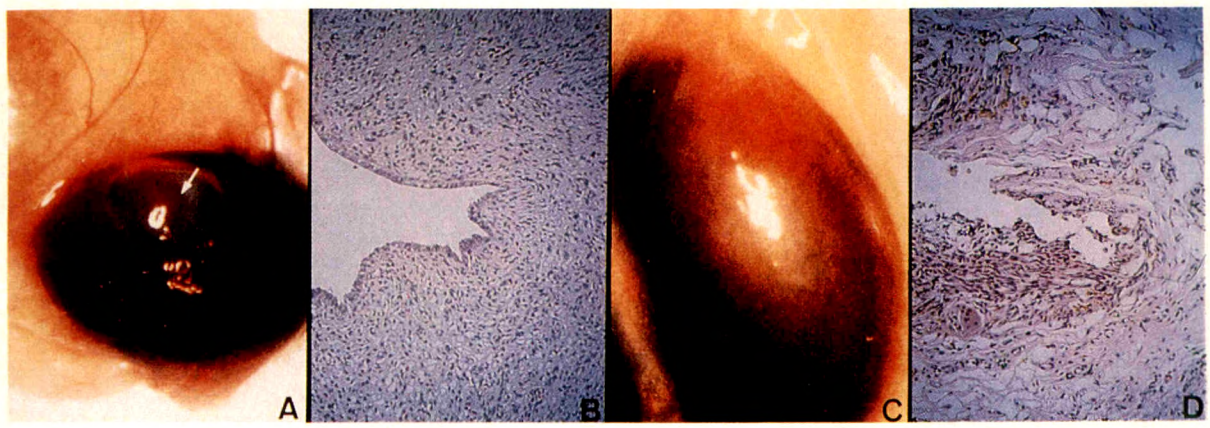

Fig. 1. Gross and microscopic appearance of experimental endometriosis at third laparotomy in intact control and ovariectomized rats. In intact control, fluid accumulates under the left renal capsule and an endometrial explant *(arrow)* is proliferative and well developed **(A)**. Histologically, both gland and stroma of the explant are well preserved **(B)**. In ovariectomized rat no fluid is found and the explant is visually absent **(C)**. Histologically, marked atrophy and regression of the explant are shown **(D)**. (Hematoxylin and eosin ×80.)

done with membrane preparations from a single pituitary by the incubation at 4° C for 4 hours. Because the affinity for specific GnRH binding sites in pituitaries of female rats was shown to be unchanged by danazol or leuprolide treatment, a saturating dose (1.25 nmol/L) of iodine 125 leuprolide, with or without 1 μmol/L of unlabeled leuprolide, was used to determine the binding sites in this study. GnRH binding sites were expressed as femtomoles per milligram of protein of pituitary gland.

Statistics. All values were expressed as mean ± SE, and analysis of variance was used for the statistical analysis. The evaluation of treatment on the regression of fluid in experimental endometriosis was analyzed statistically with the χ^2 test.

Results

All endometrial explants in 16 intact control animals were maintained essentially in the same size throughout the study (5.1 ± 0.7 mm in length × 4.4 ± 0.5 mm in width × 2.0 ± 0.2 mm in height at second laparotomy vs 4.8 ± 0.6 mm × 4.2 ± 0.5 mm × 2.0 ± 0.2 mm at third laparotomy). The gross and microscopic appearance of an explant at third laparotomy in intact control is shown in Fig. 1, *A* and *B*. Fluid accumulates under the renal capsule and the endometrial explant is proliferative and well developed. Histologically both gland and stroma of the explant are well preserved. Conversely, a complete resorption of the fluid and a marked decrease in size of the explant occurred after castration. Gross and microscopic appearance of an explant in ovariectomized rat is shown in Fig. 1, *C* and *D*. The explant is visually absent. Histologic examination also shows marked atrophy and regression of the explant.

The findings obtained in intact control and ovariectomized animals indicated that endometrial explant that is proliferating maintains essentially the same volume and shows accumulated fluid. Explant that became atrophic markedly reduced the volume and lost fluid. Therefore, in this study, the effectiveness of treatment on experimental endometriosis was evaluated with two separate parameters: the volume of the endometrial explant and formation of the fluid. At second laparotomy the rats with endometriosis was randomly divided to five groups of intact control, castration, danazol treatment, leuprolide treatment, and danazol and leuprolide combination. The volume of explants (mean ± SE) was 30.0 ± 6.2, 29.9 ± 6.8, 28.0 ± 4.8, 27.1 ± 3.8, and 27.9 ± 5.4 mm^3, respectively. The volume of explant in each individual at third laparotomy and the means of the volumes for each group are shown in Fig. 2. Although the volumes of endometrial explants in intact control rats ranged widely from 8.3 to 86.0 mm^3 (26.7 ± 5.6 mm^3), all the explants maintained essentially the same volume throughout the experiment. Endometrial explants markedly reduced to 1.4 ± 0.1 mm^3 ($p < 0.01$) in ovariectomized rats. The finding in ovariectomized animals shows that estrogen deprivation induces a marked regression of the experimental endometriosis. Endometrial explants also decreased to 11.6 ± 2.8 mm^3 ($p < 0.05$) in danazol-treated rats and to 5.9 ± 1.4 mm^3 ($p < 0.01$) in leuprolide-treated animals. It was interesting to find that the explants markedly reduced to 1.8 ± 1.0 mm^3 ($p < 0.01$) in danazol-leuprolide combination treatment. The volume of explants after the combination treatment was significantly less than that after danazol treatment ($p < 0.01$) or leuprolide treatment alone ($p < 0.05$) (Fig. 2).

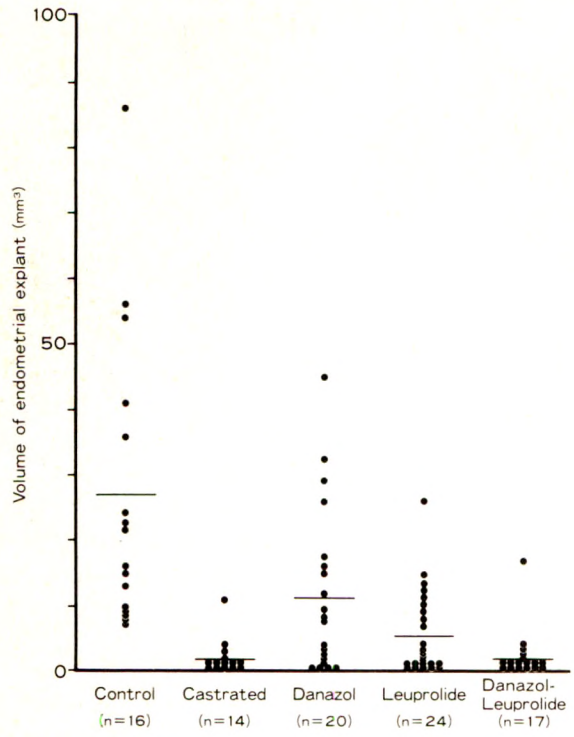

Fig. 2. Therapeutic effects of ovariectomy, treatment with danazol, leuprolide, or danazol-leuprolide combination on experimental endometriosis in female rats. The volume of endometrial explant (in cubic millimeters) in each individual at third laparotomy and the means of the volumes for each group *(solid line)* are shown. Danazol (100 mg/kg body weight per day) was administered by gastric gavage for 3 weeks and leuprolide depot formulation (1 mg/kg body weight) was injected once subcutaneously. Numbers within parentheses indicate number of treated animals. Differences from danazol-leuprolide combination; $p < 0.05$ in leuprolide alone, $p < 0.01$ in danazol alone.

With regard to formation of the fluid in the experimental endometriosis, all endometrial explants in 16 intact control rats accumulated fluid under the renal capsule. Conversely, complete resorption of the fluid accompanied by a marked atrophy of endometrial explant occurred in 13 of 14 ovariectomized rats (93%). In the remaining one the fluid accumulated. The fluid completely regressed in nine of 20 (45%) danazol-treated and in 14 of 24 (58%) leuprolide-treated animals. It was interesting to find that the fluid completely regressed in 16 of 17 (94%) animals by danazol-leuprolide combination. The therapeutic effect obtained in the combination was comparable to that obtained in castrated animals, and was significantly superior to that shown in animals treated with danazol ($p < 0.01$) or leuprolide ($p < 0.05$) alone. Serum concentrations of leuprolide and danazol in leuprolide- and danazol-treated animals were 260 ± 74 pg/ml and 31 ± 4 ng/ml, respectively. These concentrations in serum were similar to those in women who are given an effective dose of leuprolide or danazol.[11, 13]

To show the action mechanisms of these compounds on experimental endometriosis, serum concentrations of luteinizing hormone, follicle-stimulating hormone, and estradiol, and concentrations of pituitary GnRH receptors were determined under the treatment. Weights of uterus and ovaries were also measured (Table I). As expected, GnRH agonist leuprolide significantly ($p < 0.01$) decreased serum estradiol concentration as observed in castrated animals. However, serum estradiol was not decreased by danazol treatment. Serum estradiol value (38 ± 5 pg/ml) in the leuprolide-treated group was similar to the estradiol value (38 ± 4 pg/ml) in the danazol-leuprolide group (Table I). Uterine weight can be used as an index of estrogenic stimuli in female animals. We found that the changes in uterine weight under each treatment correlated well with those in serum estradiol concentrations. These results strongly suggest that the GnRH agonist leuprolide suppressed estradiol production and induced regression and atrophy of experimental endometriosis. The results also suggest that danazol possibly acted directly on the endometriotic tissues and induced atrophy. Therefore it is likely to consider that a greater response rate observed in danazol-leuprolide combination was obtained by the additive effects of danazol and leuprolide.

Despite the marked reduction in serum estradiol after leuprolide treatment, no decrease in radioimmunoassayable luteinizing hormone or follicle-stimulating hormone in serum was observed (Table I). However, leuprolide significantly reduced the concentration of pituitary GnRH receptors and the ovarian weight. These data suggest that the inhibitory effect of GnRH agonist leuprolide on estrogen production in female rats with endometriosis can be explained by a decrease in the secretion of pituitary bioactive gonadotropins but not of immunoreactive gonadotropins.

Comment

In a preliminary study endometriosis was induced in mature female rats by autotransplantation of a section of endometrium to the peritoneal wall as described by Jones.[14] However, we found some difficulties in evaluating the effects of treatment on the peritoneal endometriosis. As a result of peritoneal adhesion, the measurement of size of endometrial implant was difficult. Therefore in this study experimental endometriosis was induced under the capsule of kidney in mature female rats. The rate of induction of endometriosis in the kidney was >80%, and a precise evaluation of the effects of treatment could be achieved by

Table I. Concentrations of serum gonadotropins, serum estradiol, and pituitary GnRH receptors and weights of uterus and ovaries in control and treated groups

Treatment	Luteinizing hormone (ng/ml)	Follicle-stimulating hormone (ng/ml)	Estradiol (pg/ml)	GnRH receptors (fmol/mg protein)	Weight (mg)	
					Uterus	Ovaries
Control (n = 16)	0.9 ± 0.1	4.0 ± 0.4	73 ± 7	24 ± 5	212 ± 18	85 ± 4
Castrated (n = 14)	8.0 ± 1.2*	26.8 ± 1.7*	26 ± 7*	30 ± 5	63 ± 4*	—

the present model. All endometrial explants in intact control were viable and were maintained essentially in the same size throughout the study. Removal of the ovaries resulted in a marked decrease in the size and atrophy of the explant in all animals except one. The findings show that this animal model is useful in evaluating the effects of therapy on endometriosis. Although use of both danazol and the GnRH agonist leuprolide, which are established compounds for treatment of endometriosis, were effective in decreasing the size and inducing atrophy and regression of the experimental endometriosis in approximately half the treated animals, combination therapy with danazol and leuprolide regressed the endometriosis in 94% of treated animals. The therapeutic effect with the combination was comparable to that induced by ovariectomy. These results suggest that combination therapy with danazol and GnRH agonist is a potential modality in the treatment of endometriosis, particularly for advanced stages of the disease.

A possible mechanism of action of the compound in endometriosis was also examined in this study. GnRH agonist leuprolide did not inhibit the secretion of immunoreactive gonadotropins but reduced ovarian weight and serum estradiol in female rats with endometriosis. Pituitary GnRH receptors in the animals were markedly down regulated after leuprolide treatment. These results suggest that leuprolide suppressed ovarian estrogen production through the secretion of a qualitatively different and biologically less active gonadotropin,[15] or through direct inhibition of ovarian steroid biosynthesis.[16] We recently found that suppression of estrogen production by GnRH agonist in patients with endometriosis is induced through the suppression of the secretion of bioactive luteinizing hormone, but not through direct inhibition of ovarian estrogen biosynthesis.[4] These results, together with those of a previous study in patients with endometriosis,[4] suggest that leuprolide suppressed the secretion of bioactive gonadotropin, which resulted in the suppression of ovarian estrogen production in animals with endometriosis.

In contrast to the GnRH agonist leuprolide, danazol did not decrease concentration of serum estradiol in animals with endometriosis. In nine female rats that responded to danazol and showed regression of endometriosis, decreases in serum estradiol concentrations were not observed (88 ± 19 vs 73 ± 7 pg/ml in intact control). The dose chosen for danazol in this study appears to be adequate and not suboptimal since the serum concentrations of danazol (31 ± 4 ng/ml) 24 hours after the last administration of the compound were in the same range of those in women receiving an effective dose of the compound in the treatment of endometriosis.[11, 13] It has been suggested that danazol produces anovulation and low levels of circulating estrogen and progesterone in women by acting at the hypothalamic, pituitary, and ovarian levels.[1] However, there are several reports[17, 18] showing that danazol does not suppress serum estrogen level in women of reproductive age. We[19] and others[7] found that short-term treatment with danazol induces atrophic changes in hyperplastic and normal endometrium without a decrease in the level of serum estradiol. One possible mechanism to support these findings is the marked increase in serum concentration of free testosterone during danazol treatment.[5] Testosterone has also been shown to inhibit proliferation of endometrial cells in culture.[20] A direct inhibitory effect of danazol on the growth of normal[8] and malignant endometrial cells[9] was also demonstrated. These results, combined with the previous results, suggest that danazol either directly or indirectly, through the increase of free testosterone, acted on endometriotic tissues in female rats and induced regression and atrophy. The combination therapy with danazol and GnRH agonist, which shows a different mode

of action, seems to have an advantage in the treatment of patients with advanced endometriosis. A clinical trial is under way in our department to clarify whether the combination therapy is a potential modality in the treatment of patients with advanced endometriosis.

Uterine artery estrogen receptors in the nonpregnant and pregnant guinea pig

Joseph R. Leiberman, MD,[a] Cor C. J. van Vroonhoven, Tech.,[b] Ilse Beckmann, PhD,[c] Theo H. van der Kwast, MD,[b] and Henk C. S. Wallenburg, MD, PhD[c]

Beer Sheva, Israel, and Rotterdam, The Netherlands

Uterine artery, heart, and aorta or carotid specimens of nonpregnant, midpregnant, and term pregnant guinea pigs were examined for estrogen receptors by immnocytochemical methods. Estrogen receptors were found in the nuclei of cells in the endothelial, muscle, and adventitia layers of the uterine artery wall. The concentration of estrogen receptors was slightly higher in nonpregnant and term pregnant animals than in midpregnancy. No estrogen receptors were found in the heart, aorta, or carotid specimens of all animals. These results confirm the uterine artery as a target organ of estrogen action that would eventually lead to arterial functional adaptation in different biologic periods. (Am J Obstet Gynecol 1990;163: 1685-8.)

Key words: Uterine artery, estrogen receptor, guinea pig, estrogen action, immunocytochemical methods

It has been shown in various experiments that estrogens induce dilatation of the uterine arteries in women,[1] in the rhesus monkey,[2] the guinea pig,[3] and the ewe.[4] In the guinea pig a single injection of a medium long-acting estrogen provokes a typical widening of the mesometrial arteries[5] and stimulates deoxyribonucleic acid synthesis.[6] The effects of estrogens on the reproductive tissues are mediated by intracellular receptors.[7] Steroid-binding assays[8, 9] have been used to quantify estrogen receptor concentrations in uterine arteries, but the necessary homogenization of tissues prevented identification of cells containing estrogen receptors. The recent development of immunocytochemical methods that use monoclonal antibodies allows the intracellular detection[10, 11] and tissue localization of estrogen receptors.

The purpose of this study was to assess the presence and concentration of estrogen receptors in the uterine arterial wall of nonpregnant and pregnant guinea pigs.

Material and methods

Tissues were collected from four nonpregnant and seven pregnant albino (Hartley) guinea pigs bred in our laboratory. The guidelines for the care and use of the animals approved by the Erasmus University were followed. The animals were kept in individual cages in a controlled environment (19° C, 50% humidity) with a light/dark cycle of 13 hours/11 hours. Animals were fed commercial guinea pig pellets, hay, and water ad libitum. Vitamin C was added to the drinking water twice a week. To remove various tissues for investigation, the animals were anesthetized with ketamine hydrochloride (30 mg/kg) and xylazine (3 mg/kg) administered intramuscularly. Lidocaine 2% was added subcutaneously at the incision site. At the time of operation three of the pregnant animals were at midpregnancy (between 25 and 35 days after mating) and four were at term (between 55 and 65 days pregnant). Segments of 10 mm length were taken from the left and right uterine arteries at the proximal and distal ends. The number of fetuses in each horn was counted. Endometrium and myometrium were sampled as reference tissues. Finally, tissue samples were taken from the general vascular system, including the heart and aorta or carotid. The animals were killed by exsanguination, and blood was collected, centrifuged, and the plasma was stored at −20° C for hormone level determination. Estradiol and progesterone levels were measured by radioimmunoassay methods described previously.[12, 13]

Specimens were partially fixed in buffered 4% formaldehyde, dehydrated, and embedded in paraffin for conventional histologic study. The remaining parts were immediately frozen in chilled isopentane and stored in liquid nitrogen until use. Cryostat sections with a thickness of 6 μm were cut and fixed in a 4% formaldehyde–phosphate-buffered saline solution, pH

7.4, for 10 minutes at room temperature. After fixation the slides were incubated in chilled methanol and acetone, both at −20° C for 5 minutes and washed in phosphate-buffered saline solution (pH 7.4) for 10 to 15 minutes. The tissues were incubated with a monoclonal antiestrogen receptor antibody by means of the Abbott ER-ICA kit (Abbott, North Chicago, Ill.). The Abbott kit protocol was followed. The kit contains nonimmune goat serum, primary rat-monoclonal antiestrogen receptor antibody, linking goat-antirat antibody and the rat peroxidase-antiperoxidase complex. The immunocomplex was visualized with 3,3′-diaminobenzidine tetrahydrochloride. Two of the authors independently evaluated the staining semiquantitatively by scoring the percentage of stained cells in the tissue.

Results

Details of animal weights and plasma hormone levels are shown in Table I. The horns of the pregnant ani-

mals contained two to five fetuses. Immunocytochemical staining revealed estrogen receptors in the nucleus of the cells in endothelium, muscle, and adventitia layers of the uterine arterial wall in all three groups of animals. The percentage of stained cells was slightly higher in the nonpregnant (stained cells: 35.0% ± 16.2%, mean ± SD) and term pregnant (33.6% ± 19.8%, mean ± SD) animals than in the animals in midpregnancy (19.0% ± 17.4%, mean ± SD). A trend to higher percentages of stained cells was found in the adventitia in all three groups of animals. There were no animals without estrogen receptors in the uterine artery wall. Similar concentrations of estrogen receptors were found in the endothelial and muscle cell layers in most uterine artery segments. Proximal and distal segments of the uterine artery showed no difference in the relative number of estrogen receptors. Left and right uterine arteries had similar percentages of stained cells, and the number of fetuses in each horn had no influence on staining. The amount of stained cells of all animals was 49.9% ± 13.5% (mean ± SD) in the endometrium and 37.7% ± 4.4% (mean ± SD) in the myometrium. Heart, aorta, and carotid showed no estrogen receptors in any of the animals in the three groups.

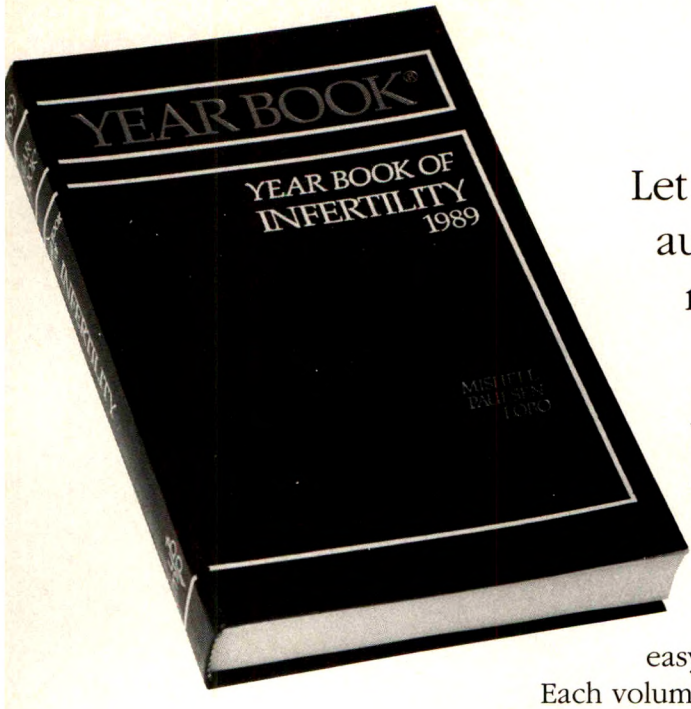
	Weight (gm)	*Estradiol (pmol/L)*	*Progesterone (nmol/L)*
Nonpregnant			
Median	787	27	11
Range	694-956	11-77	11-28
Midpregnant			
Median	777	8	340
Range	709-855	8-26	5-707
Termpregnant			
Median	1244	189	717
Range	1074-1394	143-355	159-1520

Comment

By means of immunocytochemical staining we have demonstrated the presence of estrogen receptors in the uterine artery wall of the nonpregnant and the pregnant guinea pig. The insoluble chromogen produced by the staining method was easily visualized within the nuclei of the cells. We did not assess the staining intensity because small differences in thickness of the specimen may induce optically false images of the chromogen concentration. The estrogen receptors were found in the intima, media, and adventitia of the guinea pig uterine artery. Lessey et al.[14] examined uterine tissue samples from women undergoing hysterectomy and found that vascular tissue within the sections did not bind antireceptor antibody at any stage of the cycle. In contrast, Perrot-Aplanat et al.[15] found estrogen and progesterone receptors in muscle cells of the rabbit uterus arterial bed. These authors also observed estrogen and progesterone receptors in smooth muscle cells in human endometrial spiral arteries, with strong staining at the end of the luteal phase.

We found slightly higher percentages of stained cells in uterine artery specimens from nonpregnant and term pregnant animals than in those obtained in midpregnancy. The scores for endometrial and myometrial staining were similar in all groups. This suggests a



change in estrogen sensitivity of the uterine artery in different periods of gestation, which may be related to the high progesterone/estradiol ratio we found in midpregnancy (see Table I). Because of the small number of animals, the differences were not statistically assessed.

We were not able to demonstrate estrogen receptors in the heart, aorta, and carotid. This is in agreement with Perrot-Aplanat et al.,[15] who did not observe estrogen or progesterone receptors in the rabbit myocardium, aorta, or intestinal, renal, hepatic, femoral, and pulmonary arteries. However, estrogen binding has been described by autoradiography in the muscle cells of the media of the renal artery in the rat.[16] Estradiol binding was found in rat aortic smooth muscle cells in culture.[17] Horwitz and Horwitz[18] observed estrogen binding sites in the media, adventitia, or both of the dog aorta. Estrogen binding sites were observed also in endothelial cell cultures.[19] The presence of estrogen receptors has been reported in human aorta.[20] Thus the absence of estrogen receptors in the heart, aorta, and carotid of the guinea pig may be explained by species variation or could perhaps be related to the sensitivity of the method.

We thank Frank H. de Jong, PhD, for the estimations of steroids.

Let our eminent medical authorities guide you through major new clinical advances

Introducing the

Year Book of Infertility®

This time-saving guide book makes it easy for you to keep current in your field. Each volume represents the year's most significant developments as reported in more than 800 journals and periodicals published worldwide. These selections are condensed to roughly a page in length, so you get all essential facts at a glance.

More importantly, the distinguished physician editors provide thoughtful, probing commentaries that explore the significance of each article while evaluating its practical implications for day-to-day practice.

Save hours of reading and research time and get expert guidance with this invaluable reference!

These books are published annually. For the convenience of its customers, Year Book enters each purchaser as a subscriber to future volumes and sends annual announcements of each volume approximately two months before publication. The new volume will be shipped upon publication unless you complete and return the cancellation notice attached to the announcement and it is received by Year Book within the time indicated (approximately 20 days after your receipt of the announcement). You may cancel your subscription at any time. The new volume may be examined on approval for 30 days and returned for full credit. Year Book will remove your name as a subscriber. Return postage is guaranteed by Year Book to the Postal Service.

I DEMAND A LOT FROM AN ANTIBIOTIC

MEFOXIN

...with well-documented clinical experience*

...broad coverage of important aerobes and anaerobes, including the *B. fragilis* group

...used in over 14 million patients.

BALANCED COVERAGE† WITH

MEFOXIN® IV IM

(CEFOXITIN SODIUM | MSD)

†*in vitro* activity against indicated aerobes and anaerobes

MEFOXIN is contraindicated in patients who have shown hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

MEFOXIN is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Streptococcus faecalis*) and many strains of *Enterobacter cloacae*. Methicillin-resistant staphylococci are almost uniformly resistant to MEFOXIN.

*in infections caused by indicated organisms at indicated sites

Please see following page for a Brief Summary of Prescribing Information.

BALANCED COVERAGE† WITH

MEFOXIN® IV IM

(CEFOXITIN SODIUM | MSD)

†*in vitro* activity against indicated aerobes and anaerobes

Indications and Usage: *Treatment*—Serious infections caused by susceptible strains of the designated microorganisms in the following diseases:

LOWER RESPIRATORY TRACT INFECTIONS, including pneumonia and lung abscess, caused by *Streptococcus pneumoniae,* other streptococci (excluding enterococci, e.g., *Strep. faecalis*), *Staphylococcus aureus* (penicillinase and non-penicillinase producing), *Escherichia coli, Klebsiella* species, *Hemophilus influenzae,* and *Bacteroides* species.

GENITOURINARY INFECTIONS. Urinary tract infections caused by *E. coli, Klebsiella* species, *Proteus mirabilis,* indole-positive *Proteus* (which include the organisms now called *Morganella morganii* and *Proteus vulgaris*), and *Providencia* species (including *Providencia rettgeri*). Uncomplicated gonorrhea due to *Neisseria gonorrhoeae* (penicillinase and non-penicillinase producing).

INTRA-ABDOMINAL INFECTIONS, including peritonitis and intra-abdominal abscess, caused by *E. coli, Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,* and *Clostridium* species.

GYNECOLOGICAL INFECTIONS, including endometritis, pelvic cellulitis, and pelvic inflammatory disease, caused by *E. coli, N. gonorrhoeae* (penicillinase and non-penicillinase producing), *Bacteroides* species including the *B. fragilis* group,* *Clostridium* species, *Peptococcus* species, *Peptostreptococcus* species, and group B streptococci.

SEPTICEMIA caused by *Strep. pneumoniae, Staph. aureus* (penicillinase and non-penicillinase producing), *E. coli, Klebsiella* species, and *Bacteroides* species including the *B. fragilis* group.*

BONE AND JOINT INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing).

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing), *Staph. epidermidis,* streptococci (excluding enterococci, e.g., *Strep. faecalis*), *E. coli, P. mirabilis, Klebsiella* species, *Bacteroides* species including the *B. fragilis group,** *Clostridium* species, *Peptococcus* species, and *Peptostreptococcus* species.

Although appropriate culture and susceptibility studies should be performed, therapy may be started while awaiting these results. Cefoxitin is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Strep. faecalis*) and many strains of *Enterobacter cloacae.* Methicillin-resistant staphylococci are almost uniformly resistant to cefoxitin.

Prevention—Prophylactic use in surgical procedures (e.g., hysterectomy, gastrointestinal surgery, cesarean section, transurethral prostatectomy) classified as contaminated or potentially contaminated or in patients in whom subsequent infection at the operative site would present a serious risk, e.g., prosthetic arthroplasty. MEFOXIN usually should be given ½ to 1 hour before surgery and should usually be stopped within 24 hours since continuing administration of any antibiotic increases the possibility of adverse reactions but, in the majority of surgical procedures, does not reduce the incidence of subsequent infection. However, in patients undergoing prosthetic arthroplasty, it is recommended that MEFOXIN be continued for 72 hours after the surgical procedure. If there are signs of infection, specimens for culture should be obtained for identification of the causative organism so appropriate treatment may be instituted.

Contraindications: Previous hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

Warnings: BEFORE THERAPY IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE PREVIOUS HYPERSENSITIVITY REACTIONS TO CEFOXITIN, CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. GIVE WITH CAUTION TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. IF AN ALLERGIC REACTION TO CEFOXITIN OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use. Broad-spectrum antibiotics alter normal flora of colon and may permit overgrowth of clostridia; a toxin produced by *Clostridium difficile* is a primary cause of antibiotic-associated colitis. Mild cases may respond to drug discontinuance alone; in more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte and protein supplementation, and use of a drug such as oral vancomycin; isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—Total daily dose should be reduced in patients with reduced urinary output due to renal insufficiency because high and prolonged serum antibiotic concentrations can occur from usual doses. Prescribe with caution in patients with a history of gastrointestinal disease, particularly colitis. Prolonged use may result in overgrowth of nonsusceptible organisms; repeated evaluation of the patient's condition is essential. If superinfection occurs, take appropriate measures.

Drug Interactions—Increased nephrotoxicity has been reported following concomitant administration of cephalosporins and aminoglycoside antibiotics.

Drug/Laboratory Test Interactions—High concentrations (>100 mcg/mL) may interfere with measurement of serum and urine creatinine levels by the Jaffé reaction and produce false increases of modest degree in creatinine levels reported; serum samples should not be analyzed for creatinine if withdrawn within 2 hours of cefoxitin administration. High concentrations may interfere with measurement of urinary 17-hydroxycorticosteroids by the Porter-Silber reaction and produce false increases of modest degree in levels reported. A false-positive reaction for glucose in urine has been observed with CLINITEST** reagent tablets.

Carcinogenesis, Mutagenesis, Fertility Impairment—No long-term animal study has been performed on carcinogenic or mutagenic potential. Rat studies at approximately three times maximum recommended human dosage revealed no effects on fertility or mating ability.

Pregnancy Category B—Reproduction studies in rats and mice did not reveal teratogenic or fetal toxic effects, although fetal weights were slightly decreased. In rabbits, cefoxitin was associated with a high incidence of abortion and maternal death, neither considered teratogenic. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers—Excreted in human milk: Exercise caution.

Pediatric Use—Safety and efficacy in infants from birth to three months have not yet been established. In children three months and older, higher doses have been associated with increased incidence of eosinophilia and elevated SGOT.

Adverse Reactions: The most common adverse reactions have been local reactions following intravenous or intramuscular injection. Other adverse reactions have been encountered infrequently. *Local Reactions*—Thrombophlebitis with intravenous administration; pain, induration, and tenderness after intramuscular injections. *Allergic Reactions*—Rash (including exfoliative dermatitis), pruritus, eosinophilia, fever, and other allergic reactions including anaphylaxis. *Cardiovascular*—Hypotension. *Gastrointestinal*—Diarrhea, including documented pseudomembranous colitis during or after treatment, and, rarely, nausea and vomiting. *Blood*—Eosinophilia, leukopenia including granulocytopenia, neutropenia, anemia, including hemolytic anemia, thrombocytopenia, and bone marrow depression. A positive direct Coombs test may develop in some individuals, especially those with azotemia. *Liver Function*—Transient elevations in SGOT, SGPT, serum LDH, and serum alkaline phosphatase; jaundice. *Renal Function*—Elevations in serum creatinine and/or blood urea nitrogen levels and, rarely, acute renal failure.

Note: In group A beta-hemolytic streptococcal infections, therapy should be maintained for at least 10 days to guard against the risk of rheumatic fever or glomerulonephritis. In staphylococcal and other infections involving a collection of pus, surgical drainage should be carried out where indicated. Intramuscular injections should be well within the body of a relatively large muscle such as the upper outer quadrant of the buttock (i.e., gluteus maximus); aspiration is necessary to avoid inadvertent injection into a blood vessel. The total daily dosage in infants and children should not exceed 12 grams.

How Supplied: Sterile cefoxitin sodium in vials, infusion bottles, and ADD-Vantage®† vials containing 1 gram or 2 grams cefoxitin equivalent and in 10-gram bulk bottles.

B. fragilis, B. distasonis, B. ovatus, B. thetaiotaomicron, B. vulgatus

CONSENSUS REPORT

National High Blood Pressure Education Program Working Group Report on High Blood Pressure in Pregnancy

The following paper represents a consensus by the Working Group on High Blood Pressure in Pregnancy, convened in 1988, by the National High Blood Pressure Education Program, National Heart, Lung, and Blood Institute, Bethesda, Maryland.

The publication of this report is supported by an educational grant from Merck Sharp & Dohme.

Foreword

This statement on high blood pressure in pregnancy represents a consensus between obstetricians and internists on a controversial topic in which no consensus existed previously.

The National High Blood Pressure Education Program of the National Heart, Lung, and Blood Institute, working with the American College of Obstetricians and Gynecologists, appointed a working group of physicians and scientists with expertise and experience in either hypertension or pregnancy or both. The group met five times between September 1988 and May 1989, and between the regular meetings members corresponded with each other by telephone, fax, and U.S. mail, exchanging ideas and drafts of chapters. The resulting document has been reviewed and approved by both the Coordinating Committee of the National High Blood Pressure Educational Program and the Committee on Obstetrics: Maternal and Fetal Medicine of the American College of Obstetricians and Gynecologists.

6/0/24960

The members of the Working Group were conscientious in carrying out their assignments and faithful in attending the meetings. Special citation goes to Leon Chesley, PhD, who devoted a distinguished career to this subject and whose perspective, knowledge, and good humor added immeasurably to our deliberations.

National High Blood Pressure Education Program Working Group Report on High Blood Pressure in Pregnancy

This consensus report focuses the presentation, pathophysiology, and management of the hypertensive disorders of pregnancy expanding on recommendations first presented in 1988 by the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure. Practicing physicians should determine whether a patient's hypertension during pregnancy falls into the classification of (1) chronic hypertension, (2) preeclampsia, (3) preeclampsia superimposed on chronic hypertension, or (4) transient hypertension. The distinction, for management considerations, is made between hypertension that is present before pregnancy (chronic and preexisting) and that occurring as part of the pregnancy-specific condition preeclampsia. When maternal blood pressure reaches diastolic levels of 100 mm Hg or greater, treatment should be instituted to avoid hypertensive vascular damage. The report includes a discussion of antihypertensive therapy specific to the chronic or acute hypertension occurring concomitantly with pregnancy. The roles of calcium supplementation and low-dose aspirin to prevent preeclampsia and chronic and transient hypertension are under investigation. (Am J Obstet Gynecol 1990;163:1689-1712.)

Key words: Pregnancy, hypertension, preeclampsia

Executive summary

High blood pressure complicates almost 10% of all pregnancies, and the incidence is higher if the women are nulliparous or carrying multiple fetuses. Causes of hypertension in pregnancy are multiple, and many current and previously used classification systems are elaborate and confusing, in part because of difficulty in making an etiologic diagnosis by clinical criteria alone. The consensus group recommends the schema proposed by the American College of Obstetrics and Gynecologists (ACOG) in 1972, which has been in wide use for some time, is practical and concise, and considers hypertension associated with gestation in only four categories: (1) chronic hypertension (of whatever cause but mainly essential), (2) preeclampsia, (3) preeclampsia superimposed on chronic hypertension, and (4) transient hypertension.

Preeclampsia (pure or superimposed) represents the greatest danger for the fetus and is associated with life-threatening maternal syndromes, whereas transient hypertension is a fairly benign disorder characterized by mild to moderate elevations of blood pressure late in pregnancy that return to normal post partum. Essential hypertension, also, is usually well tolerated if elevations remain (with or without therapy) below diastolic levels* of 100 mm Hg (Korotkoff phase V), but complications such as midtrimester loss, growth retardation, and abruptio placentae may occur more frequently. Because the preeclamptic syndromes and essential hypertension constitute more than three quarters of the hypertensive disorders in pregnancy, this document focuses on the presentation, pathophysiology, and management of these diseases.

Preeclampsia, a disease peculiar to pregnancy, mainly in nulliparous women, occurs primarily after gestational week 20, most frequently near term. Signs helpful in its diagnosis are presence of proteinuria, edema (especially if of recent and rapid onset), and any of the following: hemoconcentration, hypoalbuminemia, hepatic function or coagulation abnormalities, and increased urate levels. The predictive value of raised serum iron and low antithrombin III levels and hypocalciuria is under investigation.

A major pathophysiologic feature of this disease is a marked increase in peripheral resistance. This vasospasm is, in part, the result of exaggerated vascular responsiveness to circulating angiotensin II and catecholamines (and possibly an imbalance between thromboxane and prostacyclin production). Before intervention, cardiac output is often decreased, pulmonary capillary wedge pressure is normal or low, and intravascular volume is below that of normal pregnant women. Renal hemodynamics also decrease in part because of a characteristic morphologic lesion in the glomerulus, and there may be increased vascular permeability leading to albumin loss from the intravascular space. Uteroplacental perfusion is often compromised, which may lead to fetal growth retardation.

Preeclampsia can lead to two life-threatening complications. The first is a rapidly developing syndrome characterized by microangiopathic hemolytic anemia and marked signs of liver dysfunction, as well as coagulation changes. This variant, termed HELLP (hemolysis, elevated liver enzymes, low platelet count), constitutes an emergency requiring prompt termina-

*In this document diastolic blood pressure is defined as the onset of Korotkoff phase V (disappearance of sound).

tion of pregnancy. The second complication is progression of preeclampsia to a convulsive phase termed eclampsia, at one time the major cause of cerebral bleeding and maternal death in this disorder. Pending or frank eclampsia also requires immediate termination of gestation.

Therapy for preeclampsia when gestation is advanced is delivery. Severe intrapartum hypertension is controlled with intravenous hydralazine, which is successful in most instances. Favorable results have been recorded with parenteral diazoxide, labetalol, and clonidine as well as oral nifedipine. Nitroprusside should be avoided unless maternal jeopardy is extreme. Magnesium sulfate remains the drug of choice to prevent or treat eclamptic convulsions.

Women with essential hypertension often have reductions in blood pressure during the first two trimesters; failure for this to occur is an unfavorable prognostic sign. When pharmacologic intervention is required, α-methyldopa, because of its long history of safe use and a trial including a 7-year follow-up of the neonate, remains the drug of choice to treat chronic hypertension in pregnancy. Data relevant to β-blocking agents and combined β- and α-adrenergic receptor antagonists demonstrate their usefulness with little or no evidence of fetal jeopardy. Thiazide diuretics, which have been used safely in normotensive gravid women, may be used in hypertensive pregnant women, especially those who are sensitive to salt. Preliminary information concerning calcium channel antagonists is also encouraging, but angiotensin-converting enzyme inhibitors are contraindicated in pregnant women.

Finally, like all pregnant women, those with hypertension should refrain from alcohol and tobacco. The roles of calcium supplementation and low-dose aspirin (which decreases thromboxane synthesis while sparing prostacyclin production) to prevent preeclampsia and chronic and transient hypertension are under investigation.

Introduction

The hypertensive disorders during pregnancy are important causes of maternal death throughout the world, and most of these deaths are attributed to eclampsia. The hypertensive disorders also contribute extensively to stillbirths and neonatal morbidity and death. Hypertensive expectant mothers (or gravidas) are predisposed to the development of potentially lethal complications, notably abruptio placentae, disseminated intravascular coagulation, cerebral hemorrhage, hepatic failure, and acute renal failure.

The prevalence of chronic hypertension in pregnancy (that is, in those hypertensive women who become pregnant) is not known. It differs widely in different geographic areas but is probably present in 1% to 5% of all pregnancies.[1] The number of women who become hypertensive during pregnancy (preeclamptic) is also unclear, but one estimate from an indigent population is calculated to be about 13%,[2] and incidences ranging from 10% to 20% have been noted in nulliparous women.[3-6]

The purpose of this report is to provide guidance to the practicing physician in (1) managing hypertensive patients who become pregnant (hypertension that is present and observable before pregnancy or diagnosed before the twentieth week of gestation) and (2) managing pregnant patients who become hypertensive (the pregnancy-specific condition termed preeclampsia). This report expands on the recommendations of The 1988 Report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure.[7]

Classification of hypertensive disorders of pregnancy

The most important consideration in the classification of increased blood pressure during pregnancy is the differentiation of hypertension that antedates pregnancy from a pregnancy-specific condition, which is characterized by poor perfusion of many organs and usually has increased blood pressure as one of its features. In the former condition, elevated blood pressure is the cardinal pathophysiologic feature, whereas in the latter increased blood pressure is important primarily as a sign of the underlying disorder. As might be expected, the impact of these two conditions on mother and fetus is quite different, as is their management. Unfortunately, attempts to differentiate these two classes of patients have led to confusion in terminology worldwide. The system proposed by the ACOG in 1972,[8] although imperfect, has been in wide use for some time and has the advantage of clarity and simplicity.* According to this terminology, women with increased blood pressure are divided into the following groups:

- Chronic hypertension
- Preeclampsia-eclampsia
- Preeclampsia superimposed on chronic hypertension
- Transient hypertension

Chronic hypertension. Chronic hypertension is defined as hypertension that is present and observable before pregnancy or that is diagnosed before the twentieth week of gestation. Hypertension is defined as a blood pressure equal to or greater than 140/90 mm

*More recent classifications are available from the ACOG,[9] World Health Organization (WHO),[10] and the International Society for the Study of Hypertension.[11] This working group elected to use this earlier classification scheme for purposes of clarity.

Hg. Hypertension that is diagnosed for the first time during pregnancy and persists beyond the forty-second day post partum is also classified as chronic hypertension.

Preeclampsia-eclampsia. The pregnancy-specific condition is termed preeclampsia in the ACOG classification[8] and usually occurs after 20 weeks' gestation (or earlier with trophoblastic diseases such as hydatidiform mole or hydrops). It is determined by increased blood pressure accompanied by proteinuria, edema, or both. Either of the following criteria suffice for the diagnosis of hypertension in this situation: (1) systolic blood pressure increases of 30 mm Hg or greater or (2) diastolic blood pressure increases of 15 mm Hg or greater from early values (average of values before 20 weeks' gestation). If prior blood pressure is not known, readings of 140/90 mm Hg or greater after 20 weeks' gestation are considered sufficiently elevated to satisfy the blood pressure criteria of preeclampsia. Note, however, that many young pregnant women will show the blood pressure increase required for the diagnosis of preeclampsia without increasing their pressure to 140/90 mm Hg.

In preeclampsia and eclampsia the blood pressure often is widely variable from moment to moment, and two observers measuring the blood pressure successively may obtain very different readings

Proteinuria is defined as the excretion of 0.3 gm or greater in a 24-hour specimen. This will usually correlate with 30 mg/dl ("1+ dipstick") or greater in a random urine determination. Proteinuria usually is a late sign in the course of preeclampsia; although it is nonspecific, its appearance greatly bolsters the diagnosis of preeclampsia. Edema is diagnosed as clinically evident swelling, but fluid retention may also be manifested as a rapid increase of weight without evident swelling.

Preeclampsia always presents potential danger to mother and infant. However, certain signs are particularly ominous:

- Blood pressure of 160 mm Hg or more systolic or 110 mm Hg or more diastolic
- Proteinuria of 2.0 gm or more in 24 hours (2+ or 3+ on qualitative examination); *the proteinuria should occur for the first time in pregnancy and regress after delivery*
- Increased serum creatinine values (>1.2 mg/dl unless known to be elevated previously)
- Platelet count less than 100,000 μl or evidence of microangiopathic hemolytic anemia (with increased lactic acid dehydrogenase)
- Elevated hepatic enzymes (alanine aminotransferase or aspartate aminotransferase)
- Headache or other cerebral or visual disturbances
- Epigastric pain
- Retinal hemorrhage, exudates, or papilledema; *these are extremely rare and it is most unlikely that they would occur in the absence of other major signs of severe disease; when present, these signs almost always denote underlying chronic hypertension*
- Pulmonary edema

Eclampsia is the occurrence of seizures in a patient with preeclampsia that cannot be attributed to other causes.

Preeclampsia superimposed on chronic hypertension. There is ample evidence that preeclampsia may occur in women already hypertensive (i.e., who have chronic hypertension), and the prognosis for mother and fetus is much worse than with either condition alone. The Committee on Terminology[8] recommended that the diagnosis be made on the basis of increases of blood pressure (30 mm Hg systolic or 15 mm Hg diastolic or 20 mm Hg mean arterial pressure) together with the appearance of proteinuria or generalized edema.

Transient hypertension. Transient hypertension is the development of elevated blood pressure during pregnancy or in the first 24 hours post partum without other signs of preeclampsia or preexisting hypertension. This condition is often predictive of the eventual development of essential hypertension. This is obviously a retrospective diagnosis, and if any uncertainty regarding the diagnosis exists, these patients should be managed as if they had preeclampsia.

Problems with classification. Problems are inherent in the use of blood pressures measured in early pregnancy to diagnose chronic hypertension or to define basal blood pressure for the diagnosis of preeclampsia. Blood pressure usually decreases early in pregnancy, reaching its nadir at about the stage of pregnancy at which women usually seek obstetric care. The decrease averages 7 to 10 mm Hg for diastolic readings. In some women, obviously, blood pressure decreases more than 7 to 10 mm Hg, and the early decline and subsequent return of blood pressure to or toward prepregnant levels in late gestation will be sufficient to diagnose preeclampsia. Because women who are hypertensive before pregnancy have a greater decrease in blood pressure in early pregnancy than do normotensive women,[12] they are even more likely to be erroneously diagnosed as having preeclampsia according to blood pressure criteria.

It is well established that seizures as a result of eclampsia may occur when the blood pressure is only mildly increased.[13, 14] Therefore any rise in blood pressure in a pregnant woman is potentially dangerous, and the final diagnosis of "mild" or "severe" preeclampsia should not be made until after the patient is delivered and returns home.

Even the triad of proteinuria, edema, and hyperten-

sion is nonspecific; each sign could be the result of conditions other than preeclampsia. Edema is a physiologic finding present in many normal pregnant women. There is no reason to believe that the normal physiologic edema of pregnancy should not occur in women with transient hypertension, but when it does the clinically oriented classification calls for the diagnosis of preeclampsia (almost always "mild preeclampsia"). Transient hypertension is sometimes the preproteinuric phase of preeclampsia and sometimes the recurrence of chronic hypertension abates in midpregnancy, but more often it seems to be a manifestation of latent essential hypertension brought to light by pregnancy, as several follow-up studies have shown.[15-17] Transient hypertension has a high rate of recurrence in later pregnancies (up to 88%) and probably is the usual basis for the erroneous diagnosis of preeclampsia in multiparous women.

The diagnosis of superimposed preeclampsia is especially difficult. Women fulfilling diagnostic criteria for superimposed preeclampsia may indeed have preeclampsia, but in some of these women the origin of signs may instead be renal disease, either causing the hypertension or caused by it, that may coincidentally worsen during pregnancy. Conversely, many women who actually have preeclampsia may not have been diagnosed. This is a special problem in women receiving antihypertensive therapy, in whom early stages of superimposed preeclampsia without proteinuria may be masked by therapeutic lowering of blood pressure. Superimposed preeclampsia is especially difficult to diagnose in the hypertensive woman with proteinuria at the onset of pregnancy. To aid in diagnosis, investigators have suggested using criteria such as increasing levels of serum uric acid and decreasing platelet counts.[18]

Preeclampsia has a clinical spectrum ranging from mild to severe forms and then potentially to eclampsia. Affected patients do not "catch" eclampsia but progress through this spectrum. In most cases progression will be slow and the disorder may never proceed beyond mild preeclampsia. In others the disease may progress more rapidly, changing from mild to severe in days to weeks. In the most serious cases, progression may be fulminant, with mild preeclampsia evolving to severe preeclampsia or eclampsia within days or even hours. *Thus for clinical management, preeclampsia should be overdiagnosed, because a major goal in managing preeclampsia is the prevention of eclampsia, primarily through timing of delivery.*

More stringent criteria must be used in the selection of cases for research studies of preeclampsia. No classification is accurate or verifiable in the absence of a good understanding of the cause of preeclampsia to permit the development of a specific diagnostic test. Definitions that depend on a numeric threshold arbitrarily imposed on a continuous spectrum of changes (e.g., rising blood pressure) create artifacts around the chosen threshold. This is particularly true of the definitions for hypertension in pregnancy and preeclampsia. A major obstacle to the advancement of our knowledge of preeclampsia-eclampsia is the publication of studies of "mild preeclampsia," because the diagnosis is likely to be erroneous in half the cases; the women may have preeclampsia, transient hypertension, or chronic hypertension that abated during much of pregnancy or any of a wide variety of renal diseases.[19]

Another problem pertinent to clinical management is that some women with pregnancy-specific pathophysiologic changes identical to those present in preeclampsia, including coagulation and liver function abnormalities, will not have the specific signs of preeclampsia sufficient to satisfy the ACOG definition.[20] These women are nonetheless at increased risk, as are their infants, and should be managed like the more typical patient with preeclampsia.

In spite of the difficulties in making the clinical diagnosis, there is no question that a pregnancy-specific condition (preeclampsia in the ACOG Committee's classification)[8] in which reduced perfusion to many organs, including the placenta, results in increased maternal and fetal morbidity and death. Unlike chronic hypertension, in which hypertension is the important pathogenic factor, in preeclampsia blood pressure is usually important primarily as a marker of disease. Also unlike chronic hypertension, which progresses slowly over the years, preeclampsia can proceed rapidly, with attendant increased risk to mother and infant. Thus it is mandatory to attempt to differentiate these disorders to appropriately manage the pregnant woman with increased blood pressure. *If a diagnosis of preeclampsia cannot be excluded, it is most appropriate to manage the woman as though she had preeclampsia.*

Blood pressure in normal pregnancy and the epidemiology of hypertensive disorders

As noted previously, diastolic pressure decreases by an average of about 7 to 10 mm Hg early in gestation, with a rise to or toward the (assumed) prepregnancy levels in the third trimester. Only minimal changes in the systolic pressure seem to occur, which is reasonable because the increase of 30% to 40% in the cardiac output largely offsets the decrease in total peripheral resistance.

The following factors predispose to preeclampsia-eclampsia:

- Primigravid women are from six to eight times more susceptible than are multiparous women.[21]
- About one third of primigravid women who have had eclampsia have hypertension in about 20% of

later pregnancies, but generally they have mere rises in blood pressure alone (transient hypertension) rather than preeclampsia. Only 10% to 15% have proteinuric hypertension.[1] Transient hypertension, usually miscalled mild preeclampsia in the past as well as in some current classifications, recurs in 80%[16] to 88%[15] of women pregnant again and often portends ultimate chronic hypertension.

- Multiparous women who have had preeclampsia or eclampsia usually have some predisposing factor, often chronic hypertension; in these women the recurrence of superimposed preeclampsia may be as high as 70%.[1]
- The tendency for preeclampsia is inherited.[22]
- Twin pregnancy increases the risk five times.[21]
- Diabetes is a potent factor, but relative risk cannot be specified because diabetic persons often have other forms of hypertension that confuse the diagnosis.[23]
- Large, rapidly growing hydatidiform moles increase the risk 10 times in both primigravid and multiparous women.[24]
- Fetal hydrops increases the risk 10 times in both primigravid and multiparous women.[25]

Relative risk of chronic hypertension cannot be estimated because the incidence of superimposed preeclampsia varies greatly as diagnosed and is greatly overdiagnosed from one center to another.

Contrary to popular belief, hydramnios alone[26] and social class[27] do not predispose to preeclampsia, which has the same incidence in white and black American women. Lack of prenatal care may lead to failure to recognize this condition in its early stages. Black women in the childbearing age have two to three times the prevalence of essential hypertension than white women. In black women frank and latent chronic hypertension and transient hypertension often are misdiagnosed as preeclampsia.

Pregnancy can be considered a screening test for ultimate chronic hypertension because women with normotensive pregnancies, especially after age 25 years, have a low likelihood of developing later chronic hypertension; women with transient hypertension have a high probability of ultimate essential hypertension. Preeclamptic and eclamptic hypertension predict nothing, because the disorder does not permit the screening. Had it not been for the intercurrent and unrelated preeclampsia, the pregnancy could have been either normotensive or complicated by transient hypertension.

The pathology and pathophysiology of hypertension in pregnancy focusing on preeclampsia

Vasospasm. Vasospasm is presumed basic to the pathophysiology of preeclampsia-eclampsia. Vascular constriction causes resistance to blood flow and subsequent arterial hypertension. In some presentations the cardiac output is not maintained, and the resulting absent or mild hypertension underestimates the severity of the disorder. In this context it should be noted that there is good evidence for the condition of "normotensive preeclampsia."[28] Vasospasm and associated vascular damage that cause endothelial cell leaks, together with local hypoxia of surrounding tissues, presumably lead to hemorrhage, necrosis, and other end-organ disturbances of severe preeclampsia.

Vascular reactivity to infused angiotensin II and catecholamines is decreased in normal pregnancy. There is an increased pressor response to some vasoactive hormones in early preeclampsia,[29] and this increased response clearly precedes the onset of hypertension.[30] Angiotensin II refractoriness, observed in normal pregnancy, may be mediated by vascular endothelial synthesis of vasodilatory prostaglandins (e.g., prostacyclin or prostaglandin E_2 or a prostaglandin-like substance). There are data suggestive that preeclampsia may be associated with inappropriately increased production of a prostaglandin with vasoconstrictor properties or either increased inactivation or diminished synthesis or release of another with vasodilator properties or a combination of these events.

Cardiovascular changes. Values obtained by invasive cardiovascular monitoring in women with severe preeclampsia and eclampsia have helped to define cardiovascular status. At least five general observations can be made[31-33]: (1) Before treatment, myocardial contractility is rarely impaired. (2) Cardiac afterload is elevated in the absence of therapeutic interventions. (3) Cardiac output varies inversely with vascular resistance. (4) Medications that reduce vascular resistance (e.g., hydralazine) result in increased cardiac output. (5) Ventricular preload, measured by central venous and pulmonary capillary wedge pressures, is usually normal or even low in severe preeclampsia and eclampsia, unless substantial volumes of fluids are administered.

Hemoconcentration is common in women with severe preeclampsia or eclampsia, and the intravascular volume expansion that is normal for pregnancy is not present or is reduced significantly.[34] The woman of average size usually has a blood volume of nearly 5000 ml during the last several weeks of a normal pregnancy, compared with about 3500 ml when nonpregnant. With preeclampsia or eclampsia, however, pregnancy-induced hypervolemia either never develops or is reduced significantly after vasospasm ensues. In the absence of hemorrhage, the intravascular compartment in these women usually is not "underfilled," because vasospasm has contracted the space to be filled. Hemoconcentration usually persists a few hours to a few days after delivery when typically the vascular system dilates,

the blood volume increases, and the hematocrit level falls. *In the woman with severe preeclampsia or eclampsia, therefore, hypertension may be exacerbated and the risk of pulmonary edema increased as the result of vigorous fluid therapy administered in an attempt to expand the contracted blood volume to normal pregnancy levels. Likewise hypovolemia can develop even with normal blood loss at delivery.*

Hematologic changes. Thrombocytopenia, although infrequently severe, is the most commonly found hematologic aberration (by routine clinical testing) associated with hypertension in pregnancy. Fibrin degradation products in serum are elevated only occasionally. Unless there is some degree of abruptio placentae, plasma fibrinogen levels do not differ remarkably from levels found late in normal pregnancy.[35]

Antithrombin III levels are lower and fibronectin levels higher in women with preeclampsia compared with normal pregnant women; these levels are consistent with those in vascular endothelial injury.[36, 37] The clinical utility of serial antithrombin III or fibronectin measurements for the diagnosis and management of preeclampsia awaits further evaluation.

The development of overt thrombocytopenia (i.e., a platelet count $<100,000/\mu l$) is an ominous sign in women with preeclampsia. Without delivery, the platelet count most often continues to decrease and may reach levels that can result in cerebral or subcapsular hepatic bleeding, as well as excessive blood loss during and after delivery, especially by cesarean section. *Maternal thrombocytopenia is not an indication for cesarean delivery.*

The cause of the thrombocytopenia is not firmly established. It has been ascribed to platelet deposition at sites of endothelial damage[35] or to an immunologic process.[38] There is no firm evidence that the fetuses-infants born to women with severe preeclampsia-eclampsia will have thrombocytopenia, despite severe maternal thrombocytopenia.[39]

Renal changes. The majority of women with preeclampsia have mild to moderately diminished renal perfusion and glomerular filtration with correspondingly elevated plasma creatinine and uric acid levels. An elevated plasma creatinine level is a late development in the evolution of preeclampsia and is often discerned only in the range that would be considered normal for nonpregnant individuals (e.g., 0.8 to 1.0 mg/dl). In some cases of severe preeclampsia, renal involvement may be profound and plasma creatinine levels may be elevated twofold to threefold over normal values in nonpregnant women. This probably is caused by intrinsic renal changes.[40] In unusual instances, preeclampsia may lead to acute tubular, and even cortical, necrosis.

Although some degree of proteinuria should be found for the diagnosis of preeclampsia-eclampsia to be reliable,[41] proteinuria usually develops late in the course of the disease, so some women may be delivered before it appears. Thus they may have "true preeclampsia" without proteinuria. This type of proteinuria is nonselective; the increased permeability includes proportionally more of larger molecular weight proteins such as transferrin and several globulins than in renal diseases with selective proteinuria. Thus abnormal albumin excretion is accompanied by increased quantities of many other proteins. Proteinuria usually recedes within 1 week after delivery and resolution of hypertension, but in exceptional cases the protein leak may take more than 1 month to heal.

Renal changes identifiable by light and electron microscopy include those in the capillary loops, which are variably dilated and contracted. The endothelial cells are swollen; deposited within and beneath these cells are fibrils, which have been mistaken for thickening and reduplication of the basement membrane. Electron microscopic studies are consistent with the view that the characteristic changes are caused by swelling of *intraglomerular* cells, primarily endothelial cells but on occasion mesangial cells. These changes, which may be accompanied by subendothelial deposits of a fibrinlike protein material, are termed *glomerular capillary endotheliosis*.[40, 42]

Hepatic changes. Severe preeclampsia may result in alterations in tests of hepatic function and integrity, including elevation of serum aspartate aminotransferase levels. The lesion most likely to account for hepatic impairment is *periportal hemorrhagic necrosis*. Bleeding from these lesions may extend beneath the hepatic capsule to form a *subcapsular hematoma*. Hepatic involvement in preeclampsia-eclampsia is serious, and it frequently is accompanied by evidence of involvement of other organs, especially the kidney and brain, along with hemolysis and thrombocytopenia.[43]

Changes in the brain. The principal postmortem lesions described in the brains of women who died of eclampsia are hyperemia, focal anemia, thrombosis, and hemorrhage.[44] Cerebral blood flow, oxygen consumption, and vascular resistance were reported as not altered in women with preeclampsia,[45] but the possibility of focal blood flow changes could not be excluded. However, cerebral oxygen consumption is reported to be decreased by 20% in eclampsia with normal blood flow, such that McCall[45] alluded to it as "histotoxic hypoxia." Nonspecific abnormalities in the electroencephalogram are common in women with eclampsia within 48 hours of seizures, but the tracings are usually normal by 3 months.[46]

Until recently, cranial computed tomographic scans usually were reported to be normal in women with

otherwise uncomplicated eclampsia. However, with more advanced equipment, nearly half of women with eclampsia have abnormal radiographic findings.[47] The most common of these findings are hypodense areas, frequently seen in the cortical areas, that correspond to areas of petechial hemorrhage and infarction.[48]

Although visual disturbances are common with severe preeclampsia, blindness, either alone or accompanying convulsions, is uncommon. Women with *amaurosis* of varying degrees usually have computerized tomographic evidence of extensive occipital lobe hypodensities. These women completely recover within 1 week. *Retinal detachment* also may cause altered vision, although it is usually one-sided and seldom causes total loss of vision. Even without surgical treatment, vision usually returns to normal within approximately 1 week.

Uteroplacental perfusion. Compromised placental perfusion caused by placental disease (failure of trophoblastic invasion of spiral arteries) and vasospasm is almost certainly a major culprit in the genesis of increased perinatal morbidity and death associated with preeclampsia. However, there are formidable problems to measuring uteroplacental blood flow in humans with preeclampsia. In an earlier study[49] it was observed that ^{24}Na injected into the intervillous space was cleared two to three times more rapidly in normotensive pregnant women than in women with preeclampsia, implying decreased uteroplacental perfusion.

These findings are supported indirectly by studies of the clearance rate of dehydroisoandrosterone sulfate through placental conversion to estradiol-17β. More recently, measurement of the velocity of blood flowing through the uterine arteries has been used to estimate uteroplacental blood flow. Using arterial velocity waveforms obtained by Doppler ultrasonography, vascular resistance is estimated by comparing systolic and diastolic waveforms. Normally the uterine vascular bed is a low-resistance circuit and flow continues throughout diastole. As resistance increases, diastolic velocity diminishes in relation to systolic velocity, and this relationship is used to estimate decreased flow. Some investigators report an increased systolic-diastolic ratio in uterine arteries of women with preeclampsia.[50, 51] It should be emphasized that the aforementioned methods do not measure perfusion.

Differential diagnosis of hypertension in pregnancy

Discussions concerning the clinical spectrum of the hypertensive disorders in pregnancy relate to those symptoms, signs, and laboratory aberrations that permit differentiation of preeclampsia (pure or superimposed) from the more benign forms of high blood pressure, mainly essential and gestational (or transient) hypertension.

The need to distinguish preeclampsia from other disorders is particularly important in the management of women in midpregnancy (before gestational week 28) and in counseling about future pregnancies. With respect to the former, patients with midterm elevations in blood pressure caused by essential hypertension may be managed conservatively even when they have moderate to severe degrees of hypertension. However, attempts to temporize in the presence of severe preeclampsia can be disastrous, as shown by Sibai et al.[52] These authors attempted conservative therapy in 60 consecutive gravida women with severe preeclampsia between the eighteenth and twenty-seventh gestational weeks. The perinatal mortality rate was 87%. Ten mothers had convulsions, two had hypertensive encephalopathy, and one had an intracerebral hemorrhage. In addition, there were five instances of severe coagulopathy, one resulting in a ruptured capsular hematoma of the liver, and three women had acute renal failure. Although there are still dissenting opinions, most authorities consider temporization of *severe* midterm preeclampsia too risky, and interruption of gestation is usually in the mother's best interest.

The second reason for establishing a correct diagnosis relates to counseling. Subsequent pregnancies are often apt to be normotensive when preeclampsia-eclampsia develops in nulliparous women, whereas preeclampsia (or high blood pressure as a result of other causes) in a multiparous woman is associated with a greater likelihood of hypertension in subsequent gestations. In summary, when hypertension complicates pregnancy, establishing an accurate diagnosis may be useful both to help clinicians assess the immediate well-being of mother and fetus and to counsel her when she seeks advice on future pregnancies.

Results from renal biopsy studies underscore the difficulty in distinguishing clinically between preeclampsia (pure or superimposed) and other causes of high blood pressure in pregnancy. Investigators continue to seek sensitive and specific tests with which to make this differentiation.[1, 19] Some tests now of historic interest only include demonstration of decreased fractional urate clearance, reduced sodium excretory capacity after infusions of hypertonic saline solution, and exaggerated pressor responses to vasopressin or after changing from lateral recumbency to a supine posture (the "roll-over" maneuver). These tests have proved unreliable or have insufficient specificity to make them clinically useful.[1]

Several additional approaches that might help in the correct diagnosis of pure or superimposed preeclampsia have been proposed recently. These include mea-

surements of plasma antithrombin III,[53] serum iron and carboxyhemoglobin,[54] and urinary excretion of calcium.[55] Currently, however, the validity of these approaches has not been proved,* and some have been challenged.[58] Other tests under study are detection of antibodies to laminin[57] and identification of serum factors that increase mitogenic activity in fibroblasts or are toxic to endothelial cells in culture.[57, 58]

Recommended laboratory tests. Laboratory tests may aid in the diagnosis and management of hypertension during pregnancy. They also provide reference data when high-risk patients are first seen for prenatal care.

High-risk patients with normal blood pressure. Gestations in women with normal blood pressure but at high risk include women with a history of increased blood pressure when not pregnant, those who have had hypertension in a previous pregnancy other than the first, and those with diabetes, collagen vascular disease, or underlying renal vascular or renal parenchymal disease (see section on Blood Pressure in Normal Pregnancy and the Epidemiology of Hypertensive Disorders). Certain baseline data, when compared with results obtained in later gestations, will assist in the early diagnosis of preeclampsia. Baseline data in such women should include hematocrit, hemoglobin, and platelet count, as well as serum creatinine and uric acid levels. If routine urinalysis demonstrates qualitative proteinuria of 1+ or greater, a 24-hour collection should be obtained, including determination of creatinine content to check for accuracy of measurement and to permit calculation of the creatinine clearance. Some might include serum albumin and serum oxaloacetic transaminase determinations in the baseline assessment, whereas others would seek these tests only in the presence of frank hypertension. These patients should also undergo ultrasonography at the initial visit for accurate dating and as a baseline for evaluating subsequent fetal growth.

Patients with hypertension before gestational week 20. Most women with hypertension before gestational week 20 have (or will have) essential hypertension, and their management is discussed in the next section. Some of these patients will be under the care of primary physicians and will have been screened for signs of secondary hypertension. If not, we recommend the approach to evaluation and diagnosis of hypertension suggested in The 1988 Report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure.[7] Finally, gravid women with preexisting or early gestational hypertension are among the population in whom secondary hypertension is more apt to be found (e.g., renal disease, renovascular hypertension, primary aldosteronism, Cushing's syndrome, and pheochromocytoma). Thus further evaluation is warranted even for minimal suspicion. For example, pheochromocytoma, although rare, has a propensity to manifest or be activated by pregnancy, and it is associated with high maternal mortality rates when undiagnosed.[60, 61] Thus suspicion warrants performance of a screening test to detect pheochromocytoma (e.g., 24-hour excretion rate of vanillylmandelic acid or metanephrines or plasma norepinephrine and epinephrine levels).

Baseline determinations of renal function (serum creatinine and uric acid levels) and platelet count can be compared with values in later pregnancy to help determine if increases in blood pressure at this time are the usual physiologic increases in blood pressure or the onset of preeclampsia. Because these fetuses are at high risk for the development of intrauterine growth retardation, baseline ultrasonography for dating and fetal size are indicated before 20 weeks' gestation.

Patients with hypertension after midpregnancy. Table I summarizes the laboratory evaluation of women with hypertension after midpregnancy and the rationale for testing them biweekly or more often if clinical circumstances lead to hospitalization of the patient. It is important to recognize that one or more of these abnormalities may be present even when blood pressure elevation is minimal. If there is a life-threatening abnormality such as coagulopathy or abnormal hepatic or renal function, it may be necessary to terminate the pregnancy despite only mild hypertension (see section of Management of Preeclampsia).

Management of hypertension in pregnancy

Management of preexisting chronic hypertension in pregnancy

Counseling. Hypertensive women considering pregnancy should be counseled before conception. They should be informed of the high likelihood of a favorable outcome in most cases of mild to moderate essential hypertension. They should be aware of the increased risk of superimposed preeclampsia and the possible complications if preexisting renal disease or systemic illness is present.

It is helpful to inform women before pregnancy of possible adjustments in life-style that may be necessary during pregnancy if the blood pressure is elevated, specifically, the possibility that restricted activity, bed rest, or even hospitalization may be advisable.

Patients with intrinsic renal disease who are normotensive and have minimal renal dysfunction usually do well in pregnancy. However, those with azotemia (creatinine >2 mg/dl or, some say, 1.5 mg/dl) and hypertension should be advised of a number of risks.[62, 63]

*Studies designed to detect preeclampsia are currently hampered by the fact that renal biopsies are rarely indicated today, and absence of morphologic correlations makes it difficult to assess the true sensitivity and specificity of test results.

These include a high incidence of superimposed preeclampsia, increased risk of perinatal morbidity and death, and the possibility that maternal renal function may deteriorate further as a result of the pregnancy.[63, 64] These concerns are especially applicable to women with renal transplants, in whom pregnancy should be undertaken only after consultation with a nephrologist with expertise in this area.

Nonpharmacologic treatment. Close medical supervision is the mainstay of management of pregnant women with chronic hypertension. It is preferable to control the blood pressure without medication when possible. In patients with diastolic blood pressure from 90 to 99 mm Hg, this goal is not difficult to attain, because blood pressure falls in most pregnant women during the first and second trimesters.

The strategies for nonpharmacologic treatment of hypertension during pregnancy differ from those in nonpregnant individuals. Whereas weight reduction and exercise might benefit a nonpregnant individual, these measures are not encouraged during pregnancy. Although there are no studies that address the issue of exercise in hypertensive pregnancy, given the theoretic concerns regarding the role of the uteroplacental blood flow in the pathogenesis of preeclampsia, women with chronic hypertension should not be encouraged to participate in vigorous exercise.

Restriction of activity. Bed rest is a good means of maximizing uteroplacental blood flow during pregnancy and is considered established therapy in preeclampsia. In chronic hypertension its effectiveness has not been well studied, but it is an integral feature of management. Rest has been shown to reduce premature labor, lower blood pressure, and promote diuresis.[65] Strict bed rest is rarely necessary. However, all pregnant women with elevated blood pressure, whatever the cause, should be advised to limit their activities when possible and set aside time during the day when they can be "off their feet." Although many women may find it difficult to restrict their activity, it is helpful to explain the benefits to the patient before pregnancy so she can make adjustments in child care, her job, and other responsibilities. In patients with mild to moderate hypertension, restriction of activity may be effective in lowering blood pressure and antihypertensive medications may be avoided. It is usually advisable to hospitalize patients with severe hypertension for bed rest and medication when necessary.

Diet. Weight reduction may be helpful in reducing blood pressure in nonpregnant individuals, but it cannot be recommended during pregnancy. If a hypertensive woman is overweight and planning a pregnancy, weight reduction before pregnancy is advisable.

Pregnant women with hypertension have lower plasma volume than do normotensive women, and some studies suggest that the severity of hypertension correlates with the degree of plasma volume contraction.[66] For this reason, sodium restriction is generally not recommended during pregnancy.[67] If, however, a pregnant women with chronic hypertension is known to have salt-sensitive hypertension and has been treated successfully with a low-salt diet before pregnancy, it is reasonable to continue some sodium restriction during pregnancy. Patients with renal disease and reduced creatinine clearances are more likely to require sodium restriction for blood pressure control, and this should be continued during pregnancy. The amounts of weight gained during the pregnancy may be an indication of whether salt intake is appropriate.

Preliminary studies have shown that dietary calcium supplementation lowers blood pressure in pregnant and nonpregnant individuals.[68, 69] However, there are insufficient data to recommend its use for treatment of hypertension.

Table I. Laboratory evaluation of women who develop hypertension after midpregnancy

Test	*Rationale*
Hemoglobin and hematocrit	Hemoconcentration supports diagnosis of preeclampsia and is an indicator of severity. Values may be decreased, however, if hemolysis accompanies the disease.
Blood smear	Signs of microangiopathic hemolytic anemia (e.g., schistocytes) favor diagnosis of preeclampsia and may be present when blood pressure is only mildly elevated.
Platelet count	Decreased levels suggest severe preeclampsia.
Urinalysis	If qualitative dipstick is 1+ or greater, a quantitative measurement of protein excretion should be done. Hypertensive gravid women with proteinuria should be considered to have preeclampsia (pure or superimposed) until proved otherwise.
Serum creatinine level	Abnormal or rising levels, especially when assoicated with oliguria, suggest severe preeclampsia.
Serum uric acid level	Increased levels aid in the differential diagnosis of preeclampsia and are an indicator of disease severity.
Serum oxaloacetic transaminase	Abnormal values suggest severe preeclampsia with hepatic involvement.
Lactic acid dehydrogenase	Elevated levels are associated with both hemolysis and hepatic involvement and suggest severe preeclampsia.
Serum albumin	Values may be decreased even in the absence of heavy proteinuria and may relate to "capillary leak" or hepatic involvement in preeclampsia.

Home blood pressure monitoring. The rationale for close observation of the pregnant woman with hypertension is that changes in clinical status (such as development of superimposed preeclampsia) can be recognized before they become severe. This is easier to accomplish if patients are instructed to take their blood pressures at home and keep a record of the readings. They can then contact medical personnel if the blood pressure rises significantly before a scheduled visit. Home monitoring of blood pressure is often helpful because it will enable the patient to determine how much limitation of activity is necessary to keep her blood pressure controlled. This technique also helps discriminate truly elevated blood pressure from labile blood pressure increases common in young patients. Patients who are candidates for home blood pressure monitoring should have formal instruction on the correct technique for determination of blood pressure. In addition, their equipment should be checked periodically for accuracy. Preliminary data on home blood pressure monitoring during pregnancy suggest that it is a useful adjunct to the care of the pregnant woman.[70]

Alcohol and tobacco. The use of alcohol and tobacco during pregnancy should be discouraged strongly. Both have a deleterious effect on the fetus and mother. Excessive consumption of alcohol can aggravate hypertension or raise blood pressure in the mother de novo.

Rationale for pharmacologic treatment. The majority of women with chronic hypertension in pregnancy have mild to moderate elevations in blood pressure, and therefore the risk of acute cardiovascular complications is extremely low. In the small percentage of women who have severe hypertension, the increased risk of cerebral hemorrhage, cardiac failure, and myocardial infarction necessitates close monitoring and aggressive treatment during pregnancy.

Although there is increased risk of perinatal morbidity and death when the mother has chronic hypertension,[1, 71, 72] most pregnancies in these women result in healthy, full-term infants. Women with chronic hypertension are at increased risk of development of superimposed preeclampsia, and there is evidence that most, if not all, of the increased perinatal morbidity and death associated with chronic hypertension is attributable to this complication.[73] However, the literature is conflicting. Some studies have shown that infants born to women with chronic hypertension in pregnancy who do *not* have superimposed preeclampsia do as well as those born to normotensive women.[73] Other studies report a higher perinatal loss in uncomplicated pregnancy in hypertensive women (compared with normotensive women), especially with higher levels of blood pressure.[1]

The objective in treating a pregnant woman with chronic hypertension is to minimize the short-term risks to the mother of elevated blood pressure while avoiding therapeutic maneuvers that compromise fetal well-being. The specific goals for the mother are to prevent cardiovascular complications of severe hypertension and, if possible, preeclampsia. When maternal blood pressure reaches diastolic levels of 100 mm Hg or more, treatment should be instituted to avoid hypertensive vascular damage. Some experts believe at least nonpharmacologic treatment is warranted at diastolic blood pressures of 90 mm Hg or greater.

The indications for treatment of hypertension (at diastolic blood pressures of 90 to 99 mm Hg) during pregnancy are less clear. In the nonpregnant individual, treatment of mild to moderate hypertension is recommended for prevention of long-term cardiovascular consequences of elevated blood pressure.[7]

To date, clinical trials and clinical experience have not given us a conclusive answer to the question, "Does treatment of chronic hypertension prevent preeclampsia?" Many of the clinical trials of antihypertensive therapy in chronic hypertension have evaluated treatment begun in the third trimester.[74-76] This is largely a consequence of the fact that blood pressure falls in most women during the first trimester, reaching its nadir by midpregnancy. This phenomenon occurs in patients with chronic hypertension as well, and because most patients have only mild hypertension to begin with, by midpregnancy the majority will be normotensive. Therefore it is frequently not until the third trimester, when the blood pressure rises, that treatment is begun. If superimposed preeclampsia in the patient with chronic hypertension is associated with the same placental disease as in pure preeclampsia, then the definitive morphologic changes are already present by 20 weeks. Thus, one would not expect antihypertensive medication begun in the third trimester to alter these changes. To complicate matters, patients enrolled in clinical trials that have started treatment in the third trimester are frequently a heterogeneous population and include patients with transient hypertension, preeclampsia, and chronic hypertension.

There are almost no data available that would either support or dispute the notion that early treatment of chronic hypertension (in the first half of pregnancy) prevents superimposed preeclampsia. Carefully conducted clinical trials are needed to resolve this issue.

It is not uncommon for a pregnant woman with chronic hypertension to be hospitalized because of elevated blood pressure. Early treatment of hypertension in pregnancy may reduce the need for such hospitalization, but it may obscure the diagnosis of superimposed preeclampsia, because a rise in blood pressure may be the first sign of this condition.[77] It is particularly

important to monitor women being treated for hypertension during pregnancy for signs of preeclampsia, because this condition is associated with adverse fetal outcome.

With regard to fetal well-being, several studies suggest, but do not conclusively demonstrate, benefits of treating mild to moderate hypertension during pregnancy.[78] In the largest published clinical trial demonstrating a reduction in perinatal deaths in mothers treated with methyldopa, the major intake of patients was during the second trimester, with a significant proportion entering earlier in the first half of pregnancy.[79] Because the beneficial outcome was the result of a decrease in midtrimester pregnancy losses, it is not clear whether lowering blood pressure was responsible for the improved outcome. Given the potential hazards of antihypertensive treatment during pregnancy (the possibility that medication may reduce placental blood flow or adversely affect the fetus), treatment of hypertension (at diastolic levels of 90 to 99 mm Hg) must be undertaken cautiously, weighing the risks and benefits of treatment for both mother and child at all times. Excessive reduction in blood pressure is to be avoided, and a conservative approach is recommended.

Drug treatment of chronic preexisting hypertension. The goal of treating chronic hypertension during pregnancy is the reduction of maternal risk and perhaps that of the fetus (see section on Management of Preexisting Chronic Hypertension in Pregnancy). With this goal in mind it is mandatory to establish not only the efficacy of drugs to reduce blood pressure but also the acute and long-range effects of these drugs on fetal well-being, especially (based on the mechanism of action of many antihypertensive drugs) long-range neurologic effects. So far only one drug, methyldopa, meets these criteria. Thus if feasible, methyldopa therapy should be chosen in pregnancy. If this drug is ineffective or cannot be tolerated (which happens not infrequently), alternative therapy is determined by guidelines based on limited clinical experience and rational choices based on the mechanisms by which the drugs act. It is important to point out that, in spite of theoretic concerns, none of the drugs currently used to treat hypertension other than the angiotensin-converting enzyme inhibitors have been demonstrated to increase the risk in perinatal morbidity or death within the limits of acute follow-up. The following categories of antihypertensive agents are addressed alphabetically.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS. This new class of antihypertensive agents, which act in part by inhibiting conversion of angiotensin I to angiotensin II, has become popular in the treatment of essential hypertension and hypertension associated with renal disease in nonpregnant patients because of its minimal side effects. Although no teratogenic effects have been observed in animals using these drugs, they do lower uterine blood flow and reduce fetal survival in pregnant rabbits and sheep, perhaps by decreasing uterine prostaglandin E_2 and I_2 synthesis.[80] Acute renal failure with lethal consequences has also been described in the neonates of women treated with angiotensin-converting enzyme inhibitors in the last trimester.[81-84] Because other antihypertensive agents are available, it is recommended that angiotensin-converting enzyme inhibitors be avoided during pregnancy.

β-ADRENERGIC BLOCKING AGENTS. Evidence is accumulating that β-adrenergic blocking drugs are useful and sufficiently safe in treating preexisting hypertension during pregnancy.[78, 85] There is also evidence that the combined α- and β-blocking agent labetalol (α and β antagonism ratio 1:4) is relatively safe and effective in pregnancy.[85-88] Most studies to date demonstrate equal effectiveness when β-adrenoreceptor antagonists and the combined α- and β-blocker labetalol are compared with methyldopa.[85]

Finally, despite a growing and reassuring literature of controlled trials with β- and combined β- and α-adrenoreceptor agents, we must interject a note of caution. Most studies were relatively small and gestational age at entry was usually 29 to 33 weeks, leaving unanswered the possibility that treatment of larger numbers of patients or a longer duration of drug administration may reveal adverse effects.[87, 89] For instance, Butters et al.[89] suggest that the long-term use of β-blockers predisposes to major growth retardation. Finally, although some prefer β-adrenergic blockers because they cause less somnolence than methyldopa, others continue to favor the α_2-agonists because of concern that β-blocking agents, which cross the placenta, may interfere with interpretation of fetal heart rate, as well as because of the theoretic possibility that β-blockers compromise the ability of the fetus to withstand hypoxic stress.

CALCIUM CHANNEL BLOCKERS. Calcium channel blockers have been used to treat essential hypertension for many years in Europe and recently have been introduced into the United States. Nifedipine, which has a greater effect on vascular smooth muscle than on the myocardium, has proved promising in treating hypertension. However, it is teratogenic in rats when given in doses 30 times the maximum recommended human dose. There are very few studies of its use throughout human pregnancy, although these drugs are used in later pregnancy as treatment for preterm labor, without adverse consequences.[90, 91]

CENTRALLY ACTING ADRENERGIC INHIBITORS. Methyldopa and clonidine are the two most commonly used central adrenergic antagonists and both are used during pregnancy.[92-94] Clonidine is a centrally acting adrenergic inhibitor that inhibits sympathetic output from

the central nervous system. The effect of methyldopa is more complex, but it also inhibits central sympathetic discharge. Methyldopa was the first antihypertensive agent used in the treatment of hypertension during pregnancy, so the experience with it is the longest. Follow-up studies of children born to mothers taking methyldopa throughout pregnancy have revealed normal mental and physical development in these children at 10 years of age.[95] Methyldopa given to women with essential hypertension has been demonstrated to reduce the number of midtrimester abortions without affecting neonatal survival or fetal growth.[79]

Methyldopa causes somnolence in many individuals. However, its demonstrated safety for the fetus in long-term follow-up[95] makes this the initial drug of choice in the management of chronic hypertension in pregnant women and the benchmark against which other antihypertensive agents must be tested.

DIURETICS. The use of diuretic agents in pregnancy is controversial. The primary concern is theoretic. It is known that preeclampsia is associated with a reduction of plasma volume,[95] and fetal outcome is worse in women with chronic hypertension who do not have expanded plasma volume.[97] Whether this is a cause-and-effect relationship is not clearly established. Nonetheless, women who use diuretics from early pregnancy do not have increased blood volume to the degree that usually occurs in normal pregnancy.[98] This theoretic concern must be tempered by extensive experience in several well-controlled studies with the prophylactic use of diuretics in normotensive gravid women, in whom no excess of perinatal death or morbidity was evident.[99] A metaanalysis of nine randomized trials comprised of more than 7000 subjects revealed a decrease in the tendency of these women to have edema or hypertension[100] and confirmed no increased incidence of adverse fetal effects. Based on the theoretic concerns, diuretics are usually not used as first-line drugs. However, if their use is indicated, they are safe and efficacious agents, can markedly potentiate the response to other antihypertensive agents, and are not contraindicated in pregnancy except in settings in which uteroplacental perfusion is already reduced (preeclampsia and intrauterine growth retardation).

Although data concerning the use of diuretics in pregnant women with essential hypertension are sparse, this Committee concluded that gestation does not preclude use of saluretic drugs to reduce or control blood pressure in women whose hypertension predated conception or manifested before midpregnancy. (The Joint National Committee IV recommended smaller doses of diuretics than were used previously, thus minimizing metabolic effects.[7])

VASODILATORS. Hydralazine is a vasodilator that is relatively ineffective when used alone because of the reflex tachycardia with increased cardiac output that occurs with its use. However, when hydralazine is combined with a β-adrenergic blocking agent, the reflex tachycardia is prevented, and the combination is quite effective in reducing blood pressure. Hydralazine is used extensively, usually with methyldopa, in treating preexisting hypertension in pregnancy and is considered to be safe for mother and fetus by most obstetricians. Still, one survey in Scandinavia has reported fetal thrombocytopenia.[101] Therefore its use as a first-line drug in treating pregnant women with chronic preexisting hypertension should be limited.

In summary, although this working group endorses judicious antihypertensive therapy for pregnant women with preexisting essential (chronic) hypertension (diastolic blood pressures greater than or equal to 90 mm Hg), there is no good existing evidence that the use of antihypertensive therapy improves fetal survival. Methyldopa may prevent midgestational losses.

Maternal-fetal surveillance. Whether the patient has acute or chronic hypertension, fetal surveillance is indicated. The methods for fetal surveillance are the same in both cases and the interpretation is similar. If the fetus is compromised, decision making and judgment are necessary. If intrauterine growth retardation is identified by fundal measurements and documented by ultrasonography, biophysical testing should be implemented. The amount of amniotic fluid is significant, because a decreased amount of fluid may be associated with cord problems during labor.

Nonstress testing, oxytocin challenge testing, ultrasonography, and fetal movement counts constitute the most common fetal surveillance techniques. If determination of pulmonary maturity would influence management, amniocentesis should be done to determine this before the interruption of pregnancy.

Fetal surveillance involves determining if the fetus is growing appropriately. When fundal height measurements are inappropriate, other investigative avenues such as ultrasound biophysical testing should be pursued. As long as the fetus continues to grow in an appropriate manner, it can be inferred that the placenta and uterine blood flow is appropriate.

Management of preeclampsia

Prevention of preeclampsia. Our ability to prevent preeclampsia is limited by lack of knowledge regarding its cause. The cornerstone of "prevention" in patients with preeclampsia has been identification of the high-risk individual (see section on Blood Pressure in Normal Pregnancy and the Epidemiology of Hypertensive Disorders), followed by close clinical and laboratory monitoring so that the disease process can be recognized in its early stages. Women can then be hospitalized for more intensive monitoring or delivery. Although these measures do not enable us to prevent preeclampsia,

they do help to prevent its catastrophic maternal and fetal sequelae.

Although various dietary and pharmacologic strategies (low-salt and high- or low-protein diet and diuretics) have been employed with the hope of preventing preeclampsia or minimizing its severity, none have proved effective so far. Many obstetricians consider daily rest to be effective in preventing preeclampsia or minimizing its severity in high-risk individuals, although this has not been proved.

One preventive strategy that is currently receiving a great deal of attention is the use of low-dose aspirin. At the present time many centers around the world are investigating the ability of low-dose aspirin to prevent preeclampsia. These clinical trials have been prompted by two initial encouraging reports.[102, 103] In both trials, low-dose aspirin[103] or low-dose aspirin plus dipyridamole[102] was successful in reducing the incidence of preeclampsia in the groups studied. There were no fetal or maternal complications attributable to aspirin in either study; however, the total number of women who received aspirin was fewer than 100. Two recently published trials of low-dose aspirin in moderate- and high-risk pregnant women support these earlier encouraging reports and provide evidence that the beneficial effects of aspirin are associated with selective inhibition of platelet thromboxane A_2 generation, with preservation of vascular prostacyclin generation.[104, 105] However, because aspirin in large doses is associated with hemorrhagic complications in the newborn,[106] and prostaglandins play a major role in maternal-fetal physiology, we do not recommend treatment of women at risk for preeclampsia with low-dose aspirin until large clinical trials have conclusively documented the safety and efficacy of this therapy.

Rationale for treatment. The objectives of therapy for preeclampsia are based on a philosophy of management arising from the knowledge of the pathology and pathophysiology and the prognosis of the disorder for mother and infant.

- **Delivery is always appropriate therapy for the mother but may not be so for the fetus.** For maternal health, the goal of therapy is to prevent eclampsia, *as well as other severe complications of preeclampsia.* Preeclampsia is the precursor of eclampsia, and careful antepartum observation can identify the woman at risk. Preeclampsia is completely reversible and begins to abate with delivery. Thus if only maternal well-being were considered, the delivery of all women with preeclampsia, regardless of severity of the process or stage of gestation, would be appropriate. Considering the fetus, however, one should not induce delivery in mildly preeclamptic women whose fetuses are immature but have no signs of fetal compromise. There are two important corollaries of this statement. First, any therapy for preeclampsia other than delivery must have as its successful end point the reduction of perinatal death and morbidity. Second, the cornerstone of obstetric management of preeclampsia is based on a decision as to whether the infant is more likely to survive in utero or in the nursery.
- **The signs and symptoms of preeclampsia are not of pathogenetic importance.** The pathologic and pathophysiologic changes of preeclampsia indicate that poor perfusion is the major factor leading to the derangement of maternal physiologic function and to increased perinatal mortality and morbidity rates.

Attempts to treat preeclampsia by natriuresis or the lowering of blood pressure do not alleviate the important pathophysiologic changes. In fact, natriuresis may be counterproductive and may adversely affect fetal outcome, because plasma volume is already reduced in women with preeclampsia.

- **The pathogenetic changes of preeclampsia are present long before clinical criteria leading to the diagnosis are manifest.** Several studies indicate that changes in vascular reactivity, plasma volume, and renal function antedate, in some cases by months, the increases in blood pressure, protein excretion, and sodium retention. These findings suggest that irreversible changes affecting fetal well-being may be present before the clinical diagnosis. This possibility probably explains why dietary, pharmacologic, and postural therapy is not successful when avoidance of perinatal morbidity and death is taken as the end point. If a rationale for modes of therapy other than delivery of the fetus exists, it would be to palliate the maternal condition to allow fetal maturation. However, even this rationale is controversial.

Accelerated and severe hypertension can complicate any phase of gestation. Fortunately, most of these crises occur late in pregnancy and are associated with preeclampsia; the challenge to the physician is to maintain maternal blood pressure at safe levels while effecting a delivery.

Nonpharmacologic management

MATERNAL EVALUATION. Antepartum monitoring of the mother has two goals. The first is the early recognition of the condition, because infants of mothers with even mild preeclampsia are at increased risk, and the second is to gauge the rate of progression of the condition, both to prevent eclampsia by delivery and to determine whether fetal well-being can be monitored safely by the usual intermittent observations. Ideally, identification of early changes would allow intervention before the advent of clinical symptoms. At present,

other than the early increased sensitivity to angiotensin II, which is not practical for application to widespread screening, no test has a predictive value sufficient to use clinically. Notably unsuccessful are the "rollover test" and elevated second-trimester blood pressures.

At present, clinical management is dictated by the overt clinical signs of preeclampsia. Unfortunately, proteinuria, the most valid clinical indicator of preeclampsia, is often a late change, sometimes even preceded by seizures, and so is not a useful sign for early recognition. Although rapid weight increase and facial and digital edema indicate the fluid and sodium retention characteristic of preeclampsia, they are neither universally present nor uniquely characteristic of preeclampsia. These signs are, at most, a reason for closer observation of blood pressure and monitoring of urinary protein levels. Early recognition of preeclampsia is based primarily on diagnostic blood pressure increases in the late second and early third trimesters relative to early pregnancy. Use of blood pressure changes without evidence of proteinuria as an indicator does, undoubtedly, result in the diagnosis of preeclampsia in some normal women, as well as in some with underlying renal or vascular disease. Because the goal of early diagnosis is to identify patients requiring more careful observation, however, overdiagnosis is preferable to underdiagnosis.

Once the blood pressure changes suggestive of preeclampsia appear, an office examination within 24 to 48 hours is strongly recommended or, with selected patients, blood pressure and urinary protein values must be checked at home. These measures are directed at determining how fast the condition is progressing to ensure that it is not following a fulminant course. Frequency of subsequent observations is determined by these initial observations and the ensuing clinical progression. If the condition appears stable, weekly observations may be appropriate. If it appears to be accelerating, more frequent observations, usually in the hospital, are required. The initial appearance of proteinuria is an especially important sign of progression and dictates frequent observations, which is best accomplished in the hospital.

If an increasing rate of deterioration is noted, as determined by laboratory findings, symptoms, and clinical signs, the decision to continue the pregnancy is determined day by day. Important clinical signs are blood pressure, urinary output, and fluid retention as evidenced by daily weight increase. Laboratory studies are performed at intervals of no more than 48 hours. These include examination for possible activation of the coagulation system as determined by platelet count and evaluation of renal function as measured by urinary protein excretion and serum creatinine and urate levels. In addition, subjective evidence of central nervous system involvement, such as headache, disorientation, and visual symptoms, and the presence of hepatic distention, as indicated by abdominal pain and hepatic tenderness, are equally important indicators of worsening preeclampsia.

ANTEPARTUM MANAGEMENT OF PREECLAMPSIA. There is little to suggest that therapeutic efforts alter the underlying pathophysiology of preeclampsia. Therapeutic intervention is palliative. At best it may slow the progression of the condition, but more likely it merely allows continuation of the pregnancy. Bed rest is a usual and reasonable recommendation for the woman with mild preeclampsia, although its efficacy is not clearly established. Strict sodium restriction or diuretic therapy has no role in the prevention or treatment of preeclampsia. In women with marked sodium retention as manifested by significant edema, modest sodium restriction may not alter the course of the disease but may reduce discomfort.

INDICATIONS FOR DELIVERY. Prolonged antepartum management of women with severe preeclampsia is not practiced in most centers. With improvements in neonatal care, many investigators regard delivery of women with rapidly progressing preeclampsia beyond 30 weeks' gestation to be in the best interest of not only the mother but also the fetus. When gestational age is critical (between 25 and 30 weeks), one might consider controlling maternal blood pressure along with meticulous observation of the maternal and fetal condition. Delivery is then indicated by worsening maternal symptoms, laboratory evidence of end-organ dysfunction, or deterioration of fetal condition. Whether this plan of action can effect a decrease in perinatal morbidity and mortality rates is not clear. The use of this approach with even very immature fetuses may only replace a nonviable neonate with an extremely premature one, with the attendant risk of long-range neurologic disability. Such an approach should therefore be attempted only in centers equipped to provide meticulous maternal observation and daily assessment of fetal and maternal condition.

FETAL INDICATIONS. The major consideration in decisions for delivery should usually be fetal well-being, for the reasons cited. Thus if the maternal condition is stable, delivery is indicated by signs of abnormal fetal function. If fetal growth and well-being remain normal, pregnancy should proceed to spontaneous labor. If the maternal condition is deteriorating rapidly, however, delivery is indicated for fetal well-being. With maternal deterioration, a reflection of increasingly poor perfusion of brain, kidney, and liver, uteroplacental blood flow is also likely to be compromised. In addition, the predictive value of all tests of fetal well-being is invalidated by rapid changes in the maternal and, hence, fetal condition.

MATERNAL INDICATIONS. Although fetal considerations usually dictate the timing of delivery, there are important exceptions. In the rare case in which a choice

is made to palliate maternal signs and symptoms to allow fetal growth or maturation, such efforts must be abandoned if the maternal condition worsens. Also, a potentially lethal complication of preeclampsia, hepatic rupture, cannot be prevented by any mode of therapy other than delivery. It has a mortality rate of 65%. Thus the woman with hepatic capsular distention manifested by hepatomegaly, tenderness of the liver, and abnormal hepatic function values should be delivered regardless of fetal well-being or maturity.

ROUTE OF DELIVERY. Vaginal delivery is preferable to cesarean delivery for women with preeclampsia. It is desirable, if possible, to avoid the added stress of surgery because of multiple physiologic abnormalities. Palliation for several hours should not increase maternal risk if performed appropriately. Induction should be carried out aggressively and expeditiously once the decision for delivery is made. In gestation remote from term in which delivery is indicated but fetal and maternal condition are stable enough to permit pregnancy to be prolonged 36 hours, glucocorticoids can be administered safely to accelerate fetal pulmonary maturity.

The aggressive approach to induction indicates that amniotomy be performed as soon as possible and a clear end point be formulated at the initiation of therapy, usually within 8 to 12 hours of the decision to induce delivery. A trial of induction is warranted regardless of cervical condition. Obviously, if vaginal delivery cannot be effected within the predetermined time frame, cesarean delivery should be considered. Likewise, cesarean delivery is performed for other usual obstetric indications.

A regional anesthetic such as epidural analgesia offers its usual advantages for vaginal and cesarean delivery *but does carry the possibility of extensive sympatholysis with consequent decreased cardiac output, hypotension, and impairment of already-compromised uteroplacental perfusion. This is a common problem with a spinal anesthetic, which is believed by most experts to be contraindicated in the woman with preeclampsia.* This problem can be avoided by meticulous attention to anesthetic technique and volume expansion. A regional anesthetic is not a rational means to lower blood pressure because it does so at the expense of cardiac output. Likewise, although analgesia with narcotics is not contraindicated and should be used when necesssary, there is abundant evidence that attempting to manage or prevent eclampsia with profound maternal sedation is dangerous and ineffective.

Drug treatment of hypertension related to preeclampsia. Disagreement exists on whether, and how efficiently, the uteroplacental blood flow is autoregulated. Those who liken the uterine circulation to a rigid conduit incapable of autoregulation caution against precipitous decrements in mean arterial pressure, because placental perfusion is already compromised in preeclampsia.[1, 2, 107] Others[108] prefer a more aggressive approach when treating hypertension. Resolution of this problem awaits perfection of reliable and safe methods to measure placental perfusion, followed by appropriately designed therapeutic trials. In the interim the following guidelines are recommended.

TREATMENT OF HYPERTENSION REMOTE FROM DELIVERY. As cited in several sections of this report, the palliative management of preeclampsia remote from delivery is controversial. The sole rationale is to allow maturation of the fetus and, if attempted, it must not subject the mother to undue risk. An important part of safe management is control of elevated blood pressure. In the woman with diastolic blood pressure 100 mm Hg or greater, risk is sufficient to warrant pharmacologic therapy. The therapy is solely for maternal benefit; there is neither theoretic basis nor empiric evidence that such therapy is beneficial to the fetus. If therapy is elected, methyldopa is the drug of choice. If this is not tolerated or is unsuccessful, calcium channel blockers, β-blockers, and hydralazine are reasonable additions or alternatives. Successful control of blood pressure should not be interpreted as eliminating risk for mother or infant. No evidence indicates that therapy improves fetal well-being or reduces the risk of abruptio placentae, disseminated intravascular coagulation, seizures, or other maternal risk. Both maternal and fetal assessment must be carried out meticulously regardless of the degree of blood pressure control.

TREATMENT OF ACUTE HYPERTENSION DURING DELIVERY. In the more usual situation, antihypertensive therapy occasionally may be indicated as acute palliative therapy in the woman in whom delivery is indicated. Antihypertensive agents can be withheld as long as maternal pressure is only mildly elevated. However, persistent diastolic levels of 105 mm Hg or higher should be treated.* When treatment is required, the ideal drug that reduces pressures to a safe level should:

- Act quickly
- Reduce pressure in a controlled manner
- Not lower cardiac output
- Reverse uteroplacental vascular constriction
- Result in no adverse maternal or fetal effects

The medications used to treat hypertensive crises in pregnancy are summarized in Table II. Details of their pharmacology and safety are discussed elsewhere.[85, 107, 109]

The current drug of first choice is intravenous hydralazine, which if given cautiously is successful in most instances. It has been shown to be effective against preeclamptic hypertension.[34] Although this is sometimes

*It may, however, be prudent to treat lower levels in certain situations (e.g., the young gravid woman whose recent diastolic levels were below 75 mm Hg or the woman with chronic hypertension for many years and in whom hypertensive heart disease may be present).

Table II. Guidelines for drug treatment of severe hypertension near term or during labor*

- Hydralazine administered intravenously is the drug of choice. Use low doses (start with a 5 mg intravenous bolus and then give 5 to 10 mg every 20 to 30 minutes to avoid precipitous decreases. Side effects include tachycardia and headache. Neonatal thrombocytopenia has been reported.
- Diazoxide is recommended for the occasional patient whose hypertension is refractory to hydralazine. Use 30 mg miniboluses, because maternal vascular collapse and death have been associated with the customary 300 mg dose. Side effects include arrest of labor and neonatal hyperglycemia.
- Experience with parenteral labetalol is growing, and this drug may replace diazoxide as the second-line drug.
- Favorable results have been reported with calcium channel blockers. However, if magnesium sulfate is being infused, the magnesium ion may potentiate the effect of calcium channel blockers, resulting in precipitous and severe hypotension.
- Do not use sodium nitroprusside (fetal cyanide poisoning has been reported in animal models) or diuretics (e.g., furosemide; see text). However, in the final analysis, maternal well-being will dictate the choice of therapy.

*The degree to which blood pressure should be decreased is disputed. Levels from 90 to 104 mm Hg diastolic are recommended (see text).

used as an intravenous infusion, the pharmacokinetics (maximal effect at 20 minutes; duration of action 6 to 8 hours) indicate that intermittent bolus injections are more sensible. A 5 mg bolus is given intravenously for 1 to 2 minutes. Twenty minutes later, subsequent doses are dictated by the initial response. Once the desired effect is obtained, the drug is repeated as necessary (frequently in several hours). If a total of 20 mg is administered without therapeutic response, other agents should be considered.

Diazoxide is restricted to the occasional resistant case and should be administered in small doses (30 mg boluses). Preliminary successes have been recorded when calcium channel blockers (e.g., nifedipine) have been used, and in 1989 this group of drugs was undergoing testing.[107, 110] One concern about calcium channel blockers, however, is that most patients with acute hypertension during delivery will also be receiving magnesium sulfate (see below). Magnesium may potentiate the effects of calcium channel blockers and lead to precipitous decreases in blood pressure. Nifedipine acts rapidly, causing significant reduction in arterial blood pressure within 10 to 20 minutes of oral administration. The onset of antihypertensive activity can possibly be shortened by chewing the capsule or puncturing it with several needle holes before it is swallowed. The principal side effects are headache and cutaneous flushing, but minimal reflex tachycardia may occur. Like vasodilators, calcium channel blockers may cause cessation of uterine contractions. They are used to stop premature labor without maternal or fetal side effects.

Limited data are available on the use of parenteral labetalol (which some advocate as a second-line drug), starting with 10 mg and not to exceed 1 mg/kg, or clonidine. Neither labetalol nor clonidine appears to be more effective than hydralazine. Sodium nitroprusside is chosen only after the failure of hydralazine, diazoxide, calcium channel blockers, labetalol, and clonidine because of cyanide poisoning and fetal death reported in laboratory animals.[111]

Finally, the use of potent saluretic agents such as furosemide in treating hypertensive crises at term, as adjunct therapy to the vasodilators just discussed, is condemned by most authorities but still has its advocates.[108] Given the hemoconcentration and cardiovascular hemodynamics of preeclampsia and the susceptibility of some women with this disease to either intraportal hypotension or puerperal vascular collapse, many counsel against the use of potent loop diuretics and care must be taken with all antihypertensive agents. In the last analysis, however, the mother's well-being should take precedence, even if the therapy necessary to control pressure may potentially harm the fetus.

ANTIECLAMPTIC THERAPY. The pathophysiology of eclampsia is discussed in the section on Pathology and Pathophysiology of Hypertension in Pregnancy Focusing on Preeclampsia. It is a mistake to equate the eclamptic convulsion with hypertensive encephalopathy, because *the convulsion* can arise in a seemingly stable patient manifesting only minimal elevation in blood pressure. For this reason many clinicians initiate prophylactic therapy when women with suspected preeclampsia are in labor, even if premonitory signs are absent.

Because the pathogenesis of the eclamptic convulsion is still poorly understood,[107] it is not surprising to find disagreements on how to treat women with impending convulsions or frank eclampsia.[2, 107, 112-114] Most authorities, especially in North America, use parenterally administered magnesium sulfate[34]; others prefer conventional anticonvulsant drugs such as diazepam and phenytoin. Critics of the use of magnesium sulfate stress that it crosses the blood-brain barrier very slowly[115] and has no effect on electroencephalographic abnormalities.[116] Defense of magnesium sulfate therapy has been mainly empiric, but of interest are recent observations of the effect of magnesium ions on prostaglandin metabolism. For example, Watson et al.[117] have demonstrated that magnesium at levels measured in treated patients with preeclampsia increases prostacyclin release by cultured endothelial cells from human umbil-

ical veins and plasma from women with preeclampsia treated with magnesium sulfate had similar actions. The preference for magnesium sulfate, especially in the United States, is documented by its successful use in several large series,[1, 31, 108, 117, 118] but it has never undergone a definitive controlled trial. Similarly, there is a need for more extensive data regarding the effect of both magnesium and standard anticonvulsant drugs on the neonate. Preliminary data on the effects of magnesium sulfate on fetuses are encouraging.[119]

VOLUME EXPANSION THERAPY. Just as there are advocates of saluretic agents, there are claims that volume expansion may reduce blood pressure in selected patients with preeclampsia. This approach derives from observations that plasma volume, cardiac output, and pulmonary capillary wedge pressure may be decreased in this condition, as well as from reports that infusion of colloids decreased blood pressure[33, 120] and peripheral vascular resistance,[33] despite increments in intravascular volume. However, the effects of colloid infusion are usually transient, probably because the vasculature in preeclampsia is "leaky,"[121] whereas infusion of crystalloids alone decreases oncotic pressure, which is already depressed in preeclampsia.[122] Such decrements can lead to pulmonary or cerebral edema, especially in the immediate puerperium, when oncotic pressure levels decrease further, whereas central volume and pulmonary capillary wedge pressure tend to rise.[31, 122] Thus one should be cautious concerning crystalloid infusions into women with preeclampsia during labor and until a postpartum diuresis is established. Signs suggesting poor renal perfusion (i.e., oliguria) resolve quickly after delivery, and acute renal failure is an unusual complication, even in severe preeclampsia.

OTHER CONSIDERATIONS. Invasive cardiovascular monitoring may be required in severe or complicated cases, especially during operative procedures. Criteria have recently been proposed for pulmonary artery catheterization in the patient with severe preeclampsia.[123] Many experts, however, believe that these criteria are too broad and find the indications for use of Swan-Ganz catheters (a procedure associated with a certain morbidity) relatively uncommon.[124]

Treating hypertension persisting post partum. The potential problems of serious compromise of placental perfusion and, in turn, fetal well-being that can be induced by antihypertensive agents are obviated by delivery. If there is a problem after delivery controlling persisting severe hypertension, intermittent intravenous hydralazine can be used repeatedly early in the puerperium to control it. Once repeated blood pressure readings remain near normal, the hydralazine is stopped and treatment with standard oral regimens should be started.

Several other regimens are effective for control of severe postpartum hypertension. These have been discussed in the Joint National Committee Report[7] and include infusion of nitroprusside (0.5 to 10 mg/kg/min). Labetalol, 20 to 80 mg by intravenous bolus, lowers blood pressure in 5 to 10 minutes and may be repeated at 10-minute intervals.

Acute hypertensive changes induced by pregnancy usually dissipate rapidly after delivery, certainly within the first several days. If severe hypertension persists more than 3 to 5 days, the likelihood of underlying chronic hypertension is greatly increased. In these cases oral antihypertensive therapy is begun before discharge and the woman is evaluated in 1 week. For women who were hypertensive before pregnancy, chronic treatment is likely to be necessary. If prepregnancy blood pressure was normal or unknown, it is reasonable to stop oral medication after 3 to 4 weeks and observe the blood pressure at weekly intervals for 1 month and at monthly intervals for 1 year. If hypertension recurs, treatment should be resumed.

Lactation. Many women who have been chronically hypertensive during pregnancy will have the desire to breast-feed their infants for a period of several weeks to 1 year. The concentrations of most of the antihypertensive drugs have been assessed in human breast milk and plasma[125] after single or multiple dosings and all agents studied have been detectable in the milk. However, only a few reports have evaluated whether the drug is detectable in the plasma of the breast-fed infant[126-128] or if there is any hemodynamic or adverse effect of the agent on the infant. Furthermore, there have been no clinical trials involving several subjects that have studied the cardiovascular effects of any antihypertensive agent on the breast-fed infant.

In mothers with mild hypertension who wish to breast-feed for a few months, the clinician may consider withholding medication with close observation of the maternal blood pressure. After discontinuation of the nursing period, the antihypertensive therapy should be reinstituted as appropriate. For those patients with more severe elevation of blood pressure taking a single antihypertensive agent, the clinician may consider reducing antihypertensive drug dosage with close observation of both the mother and breast-fed infant. If the mother requires multiple agents for controlling the hypertension, breast-feeding is not advisable.

Remote prognosis

Eclampsia. The weighted average prevalence of hypertension after eclampsia is 23.8%, as derived from 53 articles reporting follow-up studies of 2637 women.[1] There are only two studies of large series with long-term follow-up, and they agree that the prevalence of remote hypertension is not increased over that in unselected women matched for age and race. Bryans[129] at

the Medical College of Georgia followed up 335 women for 1 to 44 years (average 14). The average age-specific blood pressures of 168 white women at follow-up fell in the middle of averages for unselected women in three epidemiologic studies of blood pressure, and there was no excess of women with diastolic pressures of 90 mm Hg or higher. The average age-specific blood pressures of 167 black women were higher than in white women but were within the range of such pressures in unselected black women.

For an average of 33 years, Chesley et al.[130] followed up 99% of the 270 women who survived eclampsia between 1931 and 1951 in the Margaret Hague Maternity Hospital in New Jersey, with all but 3 traced to 1974. Remote deaths among the 206 women who had eclampsia when primiparous did not exceed the number expected, as derived from age-specific death rates for American women matched for age and race. Only 29% of the remote deaths were associated with hypertensive vascular disease. In contrast, three times the expected number of deaths occurred among the 64 women who had had eclampsia when multiparous, and 80% of the deaths were caused by cardiovascular-renal complications. Chronic hypertension had been known to antedate the eclampsia in several of the women. The lowest expected prevalence of hypertension among 11 epidemiologic studies of blood pressure was reported in the study by Hamilton et al.[131]; therefore their study was used as the most rigid control. The distributions of diastolic and systolic pressures at an average of 33 years after eclampsia in primiparous women were virtually identical to those of the control subjects matched for age, and there was no excess of patients with hypertension among the women with posteclampsia, whatever blood pressure might be taken as the dividing line. There was an excess of cases of hypertension among the multiparous women.

Preeclampsia. Many of the numerous articles describing follow-up studies of women thought to have had preeclampsia have found high prevalences of hypertension, and some authors have believed that preeclampsia may cause chronic hypertension in women who otherwise never would have had it. It is significant that such "residual" hypertension is more common after multiparous than after primiparous pregnancies, more common after mild than severe preeclampsia, and lowest of all after eclampsia. In a word, the more secure the diagnosis, the lower the rate of ultimate hypertension. In the past, and still in most classifications, the diagnosis of mild preeclampsia is made in women with transient hypertension (see the following section). In the unique study by Fisher et al.[19] the diagnosis of preeclampsia was confirmed by renal biopsy. The prevalence of hypertension at follow-up was about 10%, almost identical to the expected rate as derived from women in the National Health Survey when matched for age and race.

Thus the prevalence of chronic hypertension after eclampsia[129, 130] or preeclampsia[13] in primigravid women is the same as in unselected women matched for age and race. Preeclampsia-eclampsia is an intercurrent event, unrelated to chronic hypertension (except that chronic hypertension may predispose to it).

Transient hypertension. Also called gestational or late hypertension, transient hypertension is the diagnosis for mere rises in blood pressure without significant edema or proteinuria, with a return of the blood pressure to normal within 10 days after delivery. Follow-up studies by Berman,[16] Herrick and Tillman,[15] Chesley et al.,[130] Adams and MacGillivray,[17] and others indicate that transient hypertension usually recurs in later pregnancies and often predicts ultimate chronic hypertension. It probably most often is latent essential hypertension unmasked by pregnancy.

Appendix

Blood pressure measurement protocol. Accurate and consistent blood pressure measurements are essential to establish a baseline and monitor subtle changes throughout the duration of the pregnancy. Blood pressures should be taken in a standardized fashion by all personnel who see the pregnant woman during her antepartum, intrapartum, and postpartum care. In 1987 the American Heart Association (AHA) updated its standards for the fifth time since 1939 in its Recommendations for Human Blood Pressure Determination by Sphygmomanometers.[132] Although this document focuses primarily on nonpregnant populations, many of its paradigms relate to the gestational period as well.

For accurate blood pressure measurements in all clinical situations, the AHA document recommends a standardized measurement technique. This includes:

- Have the patient sit* for 5 minutes before blood pressure measurement with the arm resting on a table at heart level (using the same arm on each measurement occasion for consistency).
- Measure the bared arm for proper cuff size and have available commonly used cuff sizes for adults, notably regular and large adult cuffs with respective bladder widths of 12 and 15 cm (or in general, a bladder width of 40% of the arm circumference, ensuring a bladder length that encircles 80% of the upper arm).
- Assess for approximate systolic blood pressure level before measurement by finding where the radial pulse disappears with simultaneous palpation and inflation to disappearance.
- Maintain a slow, steady deflation rate of 2 to 3 mm Hg per second or per heartbeat when doing a reading.
- Take the average of the two readings (also recommended by the Joint National Committee) to help minimize variations in recorded blood pressure across time caused by blood pres-

*The WHO Study Group[10] notes that it probably does not matter whether the patient sits or lies slightly on the left side (15- to 30-degree tilt), provided the same position is used. For practical purposes the seated position with the arm resting at heart level is the procedure used in virtually all prenatal clinics.

sure's inherent variability (reflected in isolated readings).
- Use accurate equipment (mercury sphygmomanometer or calibrated aneroid).

It is important to remember that blood pressure measurements are influenced by the relationship of the cuff to the level of the heart (caused by hydrostatic pressure, the effect of gravity on the column of blood). Blood pressure with the cuff higher than the level of the heart will be lower; blood pressure with the cuff lower than the level of the heart will be higher. For example, the practice of taking the blood pressure in the upper arm with the woman on her side will give falsely lower readings. Each centimeter above or below heart level translates to an 0.8 mm Hg change. Thus these readings will naturally differ from those taken when the arm is appropriately at heart level (i.e., woman in supine position with the arm at her side or preferably seated with the arm resting on a standard table top).

In listening to blood pressure readings, the first of at least two consecutive beats should be recorded as phase I, the systolic pressure. The AHA recommends that the onset of phase V (disappearance of sound), marked by the last sound heard, be used for defining diastolic pressure in adults. The onset of phase IV or muffling, sometimes used in the past, is harder to recognize and is subject to greater interobserver and intraobserver variability. The vast body of epidemiologic evidence from clinical trials in nonpregnant populations, linking levels of diastolic pressure to increased cardiovascular disease risk, is based on the phase V criterion. In pregnancy phase V seems to correlate best with intraarterial pressure.[33]

However, the AHA recognized certain conditions in which phase V is absent (i.e., the Korotkoff sounds do not disappear but may be heard until the pressure in the cuff falls to near 0 mm Hg). Among these conditions are high cardiac output states including pregnancy. Also, the WHO has noted that in approximately 15% of pregnant women the diastolic pressure falls to zero before the last sound is heard. Under these conditions, phase IV is a better index of diastolic pressure than is phase V. Both the AHA and WHO advise that if the phase IV (muffled) sounds are heard to zero (absent phase V), both phase IV and phase V readings should be recorded (e.g., 148/84/0 mm Hg). It seems prudent, given that the AHA recommends recording the onset of phase V as the diastolic blood pressure in adults, coupled with the probability of an absent phase V in a certain percentage of pregnant women in whom the onset of phase IV should then be recorded, that personnel should record both readings throughout the duration of the woman's pregnancy starting at the woman's initial prenatal visit. This will help ensure that no information will be lost (e.g., baseline phase IV and V readings) and that subtle changes will be detected.

LETTERS TO THE EDITORS

Discrepancies in hemoglobin levels

To the Editors: Danskin and Neilson (Danskin FH, Neilson JP. Twin-to-twin transfusion syndrome: what are appropriate diagnostic criteria? AM J OBSTET GYNECOL 1989;161:365-9) in reporting 178 consecutive twin pregnancies commented on the difficulties in the diagnosis of twin-to-twin transfusion syndrome. In their article they state that venous blood samples were usually taken from the neonates on the first day of life. We would like to point out that this method may misdiagnose the fetal hemoglobin level.

We recently checked and noted discrepancies in hemoglobin concentrations in blood collected from the umbilical vein at delivery and in the first day of neonatal life. In 12 cases of twin pregnancy umbilical venous cord blood samples were collected at delivery and the hemoglobin estimations were compared with results from venous blood samples taken on the first day of life. Discrepancies were present in 21 of the 24 infants delivered. In the eight neonates delivered small-for-gestational-age (SGA) all had a higher value in the neonatal specimen (mean difference, 34.3 gm/L ± SD 33.0; range, 8 to 108 gm/L; $p < 0.05$). In the neonates delivered appropriate-for-gestational-age (AGA) this difference was not so evident (mean difference, 12.5 gm/L ± SD 15.1; range, 0 to 59 gm/L; $p < 0.005$). In these cases there was an increase in eight, there was no change in three, and there was a decrease in hemoglobin level in five. The mean difference for SGA neonates was significantly higher than that seen in the AGA neonates ($p < 0.05$). We suggest that the hemoglobin changes result from the rapid changes in the state of hydration in the first day of life and these changes are greater in SGA infants.

We conclude that studies that rely on differences in hemoglobin and hematocrit levels to confirm the diagnosis of twin-to-twin transfusion in the presence of monochorionic placentation should be performed on cord blood samples collected at the time of delivery. The data of Danskin and Neilson may not be accurate in diagnosis of the true incidence of twin-to-twin transfusion syndrome.

Cytogenetic uncertainties surrounding the fragile X in Martin-Bell syndrome

To the Editors: The fragile site of Xq27 first noted by Lubs[1] and later appreciated by clinical geneticists for its diagnostic significance in Martin-Bell syndrome, remained a simple curiosity during the early 1970s.[2] In recent years, many laboratories have vigorously tried to modify their methods because specific tissue culture conditions are required for the expression of the fragile site at Xq27. Consequently, many more fragile sites in the human genome have been observed. Telomeric structural changes similar in appearance to the fragile X site on the long arm of chromosomes with identical morphology to the X chromosome have created a perplexing dilemma. These sites have been incorrectly misinterpreted as fragile X in a number of patients. One such example is chromosome 6, which also has a fragile site at q26 and is often a source of error.

There are persons who have a mixed population of cells with fragile site X(q27) and fragile site 6(q26) creating difficulties in the determination of an accurate estimate of the population with fragile X cells.[3] There are some persons who have gone undetected because of an extremely low percentage of cells with fragile site on chromosome X. The task remains arduous because various patients exhibit cells with a large range (1% to 50%) of fragile X. Thus it is suggested that if fragile X occurs in >0.7% of cells in males and >1.5% of cells in females from a single culture, then this probably indicates a specific fragile X expression.[4]

Routinely, the fragile X chromosome has been identified with the G-banding method. However, the harsh treatment-effect of trypsin during G-banding often results in poor morphology of the fragile sites. Consequently, the fragile X chromosome can escape detection, especially in cases with low incidence of expression.[5,6] Alternatively, if only conventional staining (solid stain) is used, chromosome 6 can be misinterpreted as a fragile X.

In our experience the conventional staining method remains highly practical in estimating the incidence of cells with fragile X. Conventionally stained metaphases can be rapidly destained and then restained by the Q-banding technique for positive chromosomal identification of those metaphases with fragile sites (Fig. 1). This confirmative approach is highly efficient, especially in subjects with a very low percentage of cells with fragile X or those who have fragile sites that involve other autosomes. With use of this approach six of 100 cases referred to our laboratory for confirmation were determined to have been erroneously identified as fragile X. A wrong diagnosis will have serious consequences, especially in cases that are identified by prenatal diagnosis, although it is understood that the absence of fragile X does not exclude the possibility of X-linked mental retardation in fetuses.

Veena Sindwani, PhD, and Ram S. Verma, PhD

Division of Genetics, Long Island College Hospital, 340 Henry St., Brooklyn, NY 11201

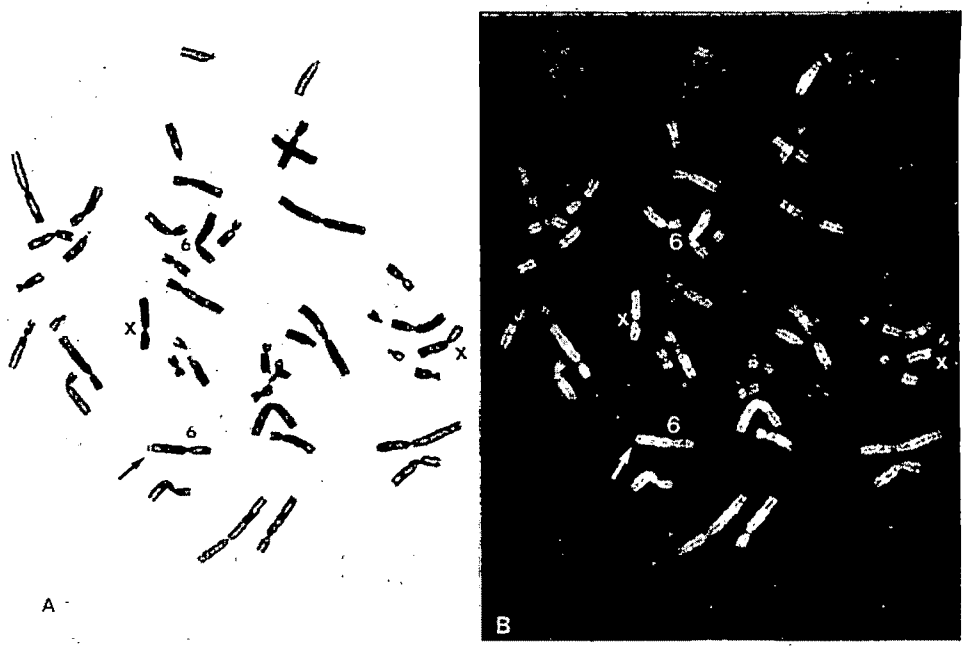

Fig. 1. A, sequentially stained metaphase from female erroneously identified as fragile X by conventional staining. **B**, same chromosome was correctly identified as chromosome 6 by Q-banding technique.

Magnesium sulfate is not an ideal anticonvulsant

To the Editors: Dr. Sibai has described magnesium sulfate as an ideal anticonvulsant (Sibai BM. Magnesium sulfate is the ideal anticonvulsant in preeclampsia. AM J OBSTET GYNECOL 1990;162:1141-5). He also implies that magnesium sulfate prevents maternal deaths. The deaths that I have studied from eclampsia have not been related to seizures, but rather to liver rupture or failure, cerebral hemorrhage, and disseminated intravascular coagulation. Some had not received magnesium sulfate, but I doubt that it would have prevented the deaths.

In our hospital, the cesarean section rate was 37.9% in parturients who received magnesium sulfate and 8.3% in those not given the drug. Much of this was because of failed induction of labor in gravida with severe preeclampsia who had an unfavorable cervix. The cases were not comparable, but I am convinced that prophylactic magnesium sulfate leads to a higher cesarean rate than would occur with use of phenytoin.

In one 4-week period, we had a patient convulse who had therapeutic levels of magnesium sulfate and another patient who received phenytoin in appropriate doses. Each responded to the other drug. Whereas magnesium sulfate may be "ideal" as Dr. Sibai has described, it is not always effective.[1]

If there is any pharmacology involved in magnesium sulfate administration, why do we use the same loading dose regardless of maternal size?

I have seen the American College of Obstetricians and Gynecologists reverse themselves on several issues (electronic fetal monitoring, prenatal Rh immune globulin, and fetal scalp sampling) and they may do so again with magnesium sulfate when younger people take the helm. Besides, I doubt whether the American College of Obstetricians and Gynecologists believes that they set the standards of obstetric care.

And finally, I wonder whether Dr. Sibai has been given an intravenous push of 6 gm of magnesium sulfate? At a patient's insistence, I have. After this dreadful experience, even if magnesium sulfate were 100% effective, I would never agree that it is an "ideal" drug, although it may be the best available.

Robert C. Goodlin, MD

Department of Health and Hospitals, City and County of Denver, 777 Bannock St., Denver, CO 80204-4507

REFERENCE

1. Sibai BM, Lipshitz J, Anderson GD, Dilts PV. Reassessment of intravenous MgSO4 therapy in preeclampsia-eclampsia. Obstet Gynecol 1981;57:199-205.

Reply

To the Editors: I thank Dr. Goodlin for his interest in the subject of the use of magnesium sulfate in preeclampsia. It is apparent that he did not get the message conveyed by my manuscript.

The emphasis of the article was on the fact that no other drug has been proved as effective as magnesium sulfate in the prevention of convulsions. I did not imply that the use of magnesium sulfate prevents maternal deaths. Maternal deaths are prevented by the experience of the staff and the availability of the appropriate facilities in a certain institution. The data on mortality were included to show that excellent maternal outcome was achieved in the absence of anticonvulsive agents other than magnesium sulfate. Thus magnesium sulfate is not a bad medicine as shown by this excellent maternal and prenatal outcome.

There are no data to indicate that cesarean section in preeclampsia is usually a result of failed induction. The rate of cesarean section for failed induction in preeclampsia is similar to the respective rate in any pregnancy being induced without the use of magnesium sulfate.

With regard to the efficacy of magnesium sulfate, I did not imply that it is universally effective. In fact, this claim cannot be made for any drug in medicine. However, I noted that the failure rates in the prevention or control of eclamptic convulsions are still superior to any other drug including phenytoin and diazepam. It is important to note that since the publication of my article, three reports appeared in the literature that indicate that magnesium sulfate is the ideal anticonvulsant in eclampsia. One report by Slater et al.[1] found recurrence of convulsions in two of eight women (25%) who received phenytoin.

Dommisse[2] reported on 22 patients with eclampsia who were randomly allocated to receive either intravenous phenytoin ($n = 11$) or magnesium sulfate ($n = 11$). Four of the 11 treated with phenytoin (36%) had further convulsions that subsequently responded to magnesium sulfate, whereas subsequent convulsions did not develop in the magnesium group. Crowther[3] reported on 51 patients with eclampsia who were randomized to receive either magnesium sulfate ($n = 24$) or diazepam ($n = 27$). Recurrent convulsion occurred in five (21%) patients in the magnesium group and seven (26%) patients in the diazepam group. In addition, the author reported that magnesium sulfate has advantages over diazepam for the mother and infant in the treatment of eclampsia.

Dr. Goodlin is worried about the painful side effects of magnesium sulfate as evident from his experience receiving it. No, I have not been given an intravenous push of 6 gm of magnesium sulfate, and will not take it to experience the effects. However, I will receive it if it ever becomes possible for me to become pregnant and develop either preterm labor or preeclampsia.

Parameters of hypothalamic aging

To the Editors: We read with great interest the study by Alexander et al. (Alexander SE, Aksel S, Hazeton JM, Yeoman RR, Gilmore SM. The effect of aging on hypothalamic function in oophorectomized women. AM J OBSTET GYNECOL 1990;162:446-9) and wish to comment on a critical issue concerning the study design and conclusions. Although the question posed by the authors is important, the study design failed to demonstrate their conclusions because the parameters assessed were not truly representative of hypothalamic aging. It is misleading to conclude from the data presented that basal, unstimulated levels of gonadotropins are representative of parameters of aging of the hypothalamic-pituitary system per se, in either rats or women.

More specifically, in reviewing the literature that examines the issue of hypothalamic aging it is apparent that aging of the reproductive system in female rats is characterized by a general decline in the frequency of regular estrous cycles. Moreover, it has been elegantly shown by Phyllis Wise that middle-aged rats (9 to 12 months old) have comparable basal concentrations of luteinizing hormone and follicle-stimulating hormone with young rats (3 to 4 months old), but show a significant and dramatic difference in the timing and amplitude of preovulatory gonadotropin surges in response to physiologic amounts of estradiol.[1] Thus it is believed that alterations in the positive feedback action of estradiol occur concurrently with the transition of regular to irregular estrous cyclicity and that these alterations represent parameters of aging of the female rat hypothalamic-pituitary axis. Therefore to extrapolate from available data about rats to women one would not expect a demonstrable difference of basal luteinizing hormone and follicle-stimulating hormone pulsatility between oophorectomized women of different ages. Basal levels are not representative of aging hypothalamic function, although estradiol-induced luteinizing hormore surges may be.

Reply

To the Editors: We thank Drs. Seifer and Jones for their interest in our study and their comments. Our work solely addressed the issue of hypothalamic aging with respect to gonadotropin-releasing hormone/leutinizing hormone (LH) secretory function in young to old women in total absence of ovarian steroids. Because release of gonadotropin-releasing hormone is reflected in the pulsatile secretion of LH, we specifically searched for age-related changes in the hypothalamus with respect to pulse frequency and amplitude in different age groups. Nowhere in the article did we extrapolate from available data about rats to women and it was of interest to us that an article by Karpas et al., who reported the pattern of pulsatile LH secretion in young, middle-aged, and old castrated male rats, followed our study design.[1] This study showed lower mean LH levels and LH pulse amplitude in the middle-aged and old rats when compared with young rats. The old rats also had significantly lower LH pulse frequency than that of the other two groups. The contention of Drs. Seifer and Jones that changes in basal LH and follicle-stimulating hormone pulsatility are not representative of aging hypothalamic function is certainly not supported by this study.

Their objection to our conclusion is apparently made on the basis of the study by Wise, as quoted in their letter, who studied young and middle-aged rats, ovariectomized and estrogen primed, but not old, anestrous rats, nor their basal gonadotropin pulse patterns. Hypothalamic response to steroids may be altered in aging rats and may possibly be altered in aging women, but we did not attempt to address this issue in our study.

Triplet pregnancies—Are we really doing better?

To the Editors: In the past 2 years there have been several articles on multifetal pregnancies, such as the one from Toronto by Dr. Gonen et al. (Gonen R, Heyman E, Asztalos EV, et al. The outcome of triplet, quadruplet, and quintuplet pregnancies managed in a perinatal unit: obstetric, neonatal, and follow-up data. AM J OBSTET GYNECOL 1990;162:454-9). The data presented are very interesting. Especially impressive are the data on survival and long-term prognosis of triplets. The conclusions of the authors were that early diagnosis, meticulous antenatal care, early hospitalization, delivery by cesarean section, and availability of expert neonatologic care are the major determinants of improved outcome. However, in a review of their data and ours[1] it is clear that despite various antenatal efforts, such as early diagnosis, hospitalization and use of tocolysis, in the past 4 decades we could not prolong the mean gestational age at delivery or the average infant weight of triplets. As for early hospitalization, it has been shown that equally good results can be achieved by outpatient management of triplet pregnancies.[2]

We believe that the better prognosis for triplets could be attributed primarily to the great advances in neonatology, whereas our role as obstetricians in these cases is somewhat limited. However, it should not be implicated that advanced obstetric care is futile. We would very much like the authors to share with us their opinion on the issue because we are sure that not all hospitals have the excellent neonatologic facilities and abundance of personnel as the one with which they are associated in Toronto.

2. Newman RB, Hamer C, Miller MC. Outpatient triplet management: a contemporary review. AM J OBSTET GYNECOL 1989;161:547-55.

Reply

To the Editors: Drs. Weisman and Jacobi make some excellent points. There is no doubt that many of the interventions notated have not been proved prospectively by randomized trials in either singleton or triplet pregnancies. Thus they could be concluded to be contentious. Despite the fact that our review was not set up to evaluate the individual components or weight their importance, I agree that there can be no doubt that quality of neonatal care at the time of delivery and a highly functional team effort in the neonatal intensive care unit are absolutely necessary and quite possibly of the most significance.

However, I think if one looked at outcome over time with specific reference to stillbirths one might find, as we have with singleton pregnancies, that over the past 20 years the stillbirth rate has fallen as well as the neonatal death rate; with a significant incidence of intrauterine growth retardation in triplets (17%) one might also find with the passage of time that there also was a decrease in morbidity. Both of these factors might well relate to the importance of quality obstetric care. Certainly the evidence from isolated neonatal intensive care after neonatal transport, as opposed to the improved neonatal outcome from integrated perinatal intensive care after fetal-maternal transport, would also suggest that the obstetric component is of some significance.

The point with respect to outpatient management versus inpatient management is contentious as well, inasmuch as the outpatient management referred to relates predominantly to monitoring of uterine activity and educational efforts by nurses (as well as frequent hospitalization, when indicated, and tocolytic therapy). As the American College of Obstetricians and Gyne-

cologists pointed out in a recent bulletin, the place of all or any of the above has not been proved in the prevention of preterm delivery. Perhaps with the widespread use of this approach at the present time in North America it will never be able to be proved adequately in hard scientific terms. We all know the difficulties we have with respect to the place and value of electronic fetal heart rate monitoring.

I think the bottom line at the present time is that when one puts the total package together one can get good results with quality care. Patients should be aware of this both at the time of in vitro fertilization and in the discussion of selective reduction before any final decision is made.

One case of 45,X abortus with high CA 125 level

To the Editors: In our report (Check JH, Nowroozi K, Winkel CA, Johnson T, Seefried L. Serum CA 125 levels in early pregnancy and subsequent spontaneous abortion. Obstet Gynecol 1990;75:742-4; submitted for publication July 27, 1989) of the relationship of CA 125 to spontaneous abortion, we included one case of a fetal karyotype of 45,X. This case led us to speculate on the possibility that an elevated CA 125 level could suggest a chromosomal abnormality. This was the only abortus that had been karyotyped in the initial series, and we were prompted to try to karyotype subsequent abortions in an effort to support our hypothesis. The question was, Is this associated only with 45,X or with other aneuploidies? After subsequently finding two additional cases, a trisomy 21 and a trisomy 12 and 13, we submitted a case report, which was published subsequently in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY (Check JH, Nowroozi K, Vaze M, Wapner R, Seefried L. Very high CA 125 levels during early first trimester in three cases of spontaneous abortion with chromosomal abnormalities. AM J OBSTET GYNECOL 1990;162:674-5; submitted for publication August 10, 1989), including not only the latter two cases but also the 45,X case. This may have inadvertently given the reader the impression that we have seen two cases of 45,X karyotype with an elevated CA 125 level. We write this letter to clarify that we have observed only one case of 45,X abortus with high CA 125 level.

We have subsequently found other cases that have also had chromosomal abnormalities, including another trisomy 21 and a trisomy 10. We are presently engaged in a prospective study aimed at determining whether elevated CA 125 levels in the early first trimester indicate an increased risk of fetal chromosomal abnormalities or whether the association is merely coincidental.

We apologize for any confusion with the reported case and want to reiterate that we reported only one case of elevated CA 125 and subsequent abortion in a fetus with 45,X karyotype.

The Baystate Medical Center is the major provider of tertiary care in Western Massachusetts. It has recently expanded its resources through its designation as the Western Campus for Tufts University Medical School. In response, the Department of Obstetrics and Gynecology is expanding its full time faculty group.

The Department has over six thousand deliveries and three thousand operative procedures. Our staff consists of forty-five community based physicians, five certified nurse midwives, and eleven full time faculty in the fields of Maternal-Fetal Medicine, Reproductive Endocrinology, Gynecologic Oncology and Primary Care. The Department has a major commitment to Student Education and has an independent Resident Education Program with twenty residents. Excellent opportunities exist for basic and clinical investigation in many areas.

Baystate Medical Center offers a salary and academic rank commensurate with experience. The Department also has a practice plan. Send Curriculum Vitae or contact:

Laurence E. Lundy, MD, Chairman, Obstetrics and Gynecology
John Powell, MD, Chief, Gynecologic Oncology
Patrick O'Grady, MD, Chief, Maternal Fetal Medicine
Halina Wiczyk, MD, Chief, Reproductive Endocrinology

OBSTETRICAN/GYNECOLOGIST
COLUMBIA, SOUTH CAROLINA

A progressive six man OB/GYN Practice with a Maternal-Fetal Medicine Specialist is seeking an additional partner to practice obstetrics and gynecology.

This practice is based at one hospital, has a new office, two ultrasound machines, and in-office laser surgery. We are very active in high risk pregnancies and operative laparoscopy.

We are looking for a board certified or board eligible, young physician to associate with this practice on a permanent basis. Salary is competitive with comprehensive fringe benefits package.

Association will lead to full and equal partnership. We are seeking a new partner as of July 1, 1991.

For more information, please send a letter and Curriculum Vitae to:

Alexander R. Smythe, II, M.D.
Columbia OB-GYN Associates, P.A.
1333 Taylor St., Suite 5-F
Columbia, South Carolina 29201

OB/Gyn or Perinatologist

Faculty appointment based full-time at affiliated hospital (500 beds, 4000 deliveries, Level III nursery) in moderate-sized city. Primarily obstetrics but little night/weekend call. Excellent opportunity for board certified/eligible generalist or perinatologist to teach & practice in environment conducive to family life. Competitive salary & benefits.

Send CV to:

Charles B. Hammond, MD
Chairman
Department of OB/Gyn
PO Box 3853
Duke University Medical Center
Durham, North Carolina 27710
or FAX 919-684-6161

BRIGHAM AND WOMEN'S HOSPITAL

Obstetrician/Gynecologist

The Brigham and Women's Hospital, a major teaching hospital of Harvard Medical School, seeks several obstetrician/gynecologists to join a busy full-time faculty group practice in general obstetrics and gynecology. The practice is located in a private setting near the hospital.

Applicants should be Board-certified/eligible.

Academic appointment at Harvard Medical School will be granted.

Offers competitive economic package and generous fringe benefits.

Commitment to clinical care and teaching are essential.

Send inquiry and curriculum vitae to:
Kenneth J. Ryan, M..D., Chairman
Department of Obstetrics and Gynecology
Brigham and Women's Hospital
75 Francis Street, ASB1-3-073
Boston, Massachusetts 02115

The Brigham and Women's Hospital is an affirmative action, equal opportunity employer.

CHAIR, DEPARTMENT OF OBSTETRICS AND GYNECOLOGY

The Allentown Hospital–Lehigh Valley Hospital Center (TAH-LVHC), an 830-bed regional tertiary care teaching hospital is seeking an OB/GYN Chair. The hospital has 33 active OB/GYN staff physicians, including a gynecologic oncologist and reproductive endocrinologist. The current Chair, who will be leaving at the end of this year, is a perinatologist. The hospital is currently recruiting a maternal-fetal subspecialist. TAH-LVHC is a regional Level III Perinatal Center and a clinical campus of Hahnemann University in Philadelphia. Of over 3,300 births in 1989, 42% were in the high-risk category. The department is supported by a 20-bed Level III NICU and has an active OB/GYN clinic which experienced over 8,000 visits in 1989.

NEWLY-CREATED POSITION OF VICE CHAIR/DIRECTOR OF EDUCATION

In response to the continuing growth of the community and the expansion of the OB/GYN Department, TAH-LVHC is seeking its first full-time OB/GYN Vice Chair/Director of Education. The hospital has a fully-approved free-standing Residency Program with eight American-trained residents. A total of 70 residents and 400 medical students are trained at the hospital each year.

The hospital is located in Allentown, a cosmopolitan city one hour north of Philadelphia and one and one-half hours west of New York City. Interested board-certified candidates may send a curriculum vitae, in confidence, to **Headley S. White, Jr., M.D., Sr. V.P., Medical and Academic Affairs, c/o HealthSearch, 50 College Drive, Suite 323, Allentown, PA 18104. (215)778-7993.**

Academic Gynecologic Oncologist

The Dartmouth-Hitchcock Medical Center is searching for a Board Certified Gynecologic Oncologist at the Associate Professor Level. He/She must be an accomplished investigator and be interested in developing a medical center and state-wide academic and clinical program in gynecologic malignancy. Please send CV with names and addresses of three references to:

Dartmouth-Hitchcock Medical Center

The Hitchcock Clinic
Hanover, New Hampshire

PERINATOLOGIST

Outstanding practice opportunity for a BC/BE perinatologist to join an established practice at Iowa's largest private teaching medical center. The hospital, a state designated Level III Perinatal Center, averages over 2,000 deliveries annually and has an active maternal and neonatal transport system. The medical center's Level III Neonatal Intensive Care Unit is staffed by four board certified neonatologists. Complete laboratory facilities are available including cytogenetic analysis of both amniotic fluid and trophoblastic tissue. The Antepartum Testing Unit is equipped with computer-based fetal monitors and a color flow Doppler ultrasound unit. Excellent financial and lifestyle opportunities are available to the qualified candidate. Please call 515/283-5911 or send CV to Mariann Clark, Medical Search Consultant, 1200 Pleasant Street, Des Moines, IA 50309.

SOUTHEASTERN KANSAS
BUILD A SUCCESSFUL PRACTICE

Progressive, 188-bed medical center, located in a beautiful, Southeastern Kansas university town, has great need for another OB/GYN. Because of over 500 deliveries in the service area, the two OB/GYN's and Family Practice physicians cannot meet the demand for both Obstetrics and Gynecology. The 28-physician medical staff will welcome you and the hospital will do everything possible to help establish your practice. Build this fine practice while enjoying a quality lifestyle in a college town. Outstanding financial package.

Send CV or call Mark Hanna at:

JACKSON AND COKER, INC.
115 Perimeter Center Place
Suite 380 AJOGO
Atlanta, GA 30346

OBSTETRICIAN/GYNECOLOGIST

Board Certified or Eligible

Lutheran General Hospital, a 713-bed teaching hospital affiliated with the University of Chicago, Pritzker School of Medicine, is recruiting a generalist to join our hospital-based clinical faculty to share in patient care and education. There are more than 5000 deliveries annually, and over 1000 major gyn cases. Our Perinatal Center is the regional referral facility for a service area with more than 12,000 births, and will soon be part of the University of Chicago Perinatal Network. A completely new labor and delivery floor oriented towards the LDR concept opens next fall, and will provide optimal space and services for high risk and normal obstetrical patients. We have an active Ambulatory Surgery Unit, and committed operating rooms for major inpatient surgery. Inpatient and outpatient laser and pelviscopy instrumentation is available, and our new IVF program has recently delivered its first baby. Our Perinatal services are supported by an active Genetics program, and a large NICU and Neonatalogy Faculty. Our hospital-based faculty now includes five Generalists, four Perinatalogists, two Gyn Endocrinologists, and two Gyn Oncologists. All faculty members will have clinical appointments at the Pritzker School of Medicine.

Clinical responsibilities involve the care of ambulatory and inpatients as part of the group, with involvement of residents and students. Our patient mix is largely private or managed care. Additional educational responsibilities include clinical and didactic teaching of Ob/Gyn, Family Practice, and Surgical residents, and medical students at 3rd and 4th year levels. Interest and experience in clinical research is valued, and matches our plans for program development. The position is available now, and we hope to fill it quickly.

Our hospital is in Park Ridge, an attractive suburb northwest of Chicago. We offer a competitive salary and benefits package that is commensurate with experience and qualifications. Please send your C.V. to: **John W. Grover, MD, FACOG, Chairman, Department of Obstetrics and Gynecology, 1775 Dempster St., Park Ridge, IL 60068, or call directly at 708/696-6994.** Equal Opportunity Employer.

Lutheran General Hospital

The Mount Sinai Medical Center of New York

Gynecologic Oncologist

An outstanding career opportunity exists within our Division of Gynecologic Oncology for an additional faculty member at the assistant or associate professor level.

The Mount Sinai Medical Center comprises the Mount Sinai School of Medicine and the Mount Sinai Hospital, a 1200-bed newly refurbished state-of-the-art comprehensive teaching center in New York City. It is affiliated with The City Hospital, Elmhurst Queens and two private hospitals.

The department sponsors a fully accredited residency program with twenty-four residents and fellowship programs for specialty certification in Maternal Fetal Medicine, Reproductive Endocrinology and Gynecologic Oncology.

We seek an individual who is interested in a career in academic medicine, becoming actively involved in research, teaching and patient care. We offer a highly competitive benefit package including professional liability coverage, medical and dental coverage, pension, continuing education, vacation, sick time, as well as housing assistance.

For consideration, please direct your letter, curriculum vitae and the names of three references to: Carmel J. Cohen, MD, Director, Gynecologic Oncology, Dept of Obstetrics, Gynecology, & Reproductive Science, Box 1175, One Gustave L. Levy Place, New York, NY 10029 -6574. An Equal Opportunity Employer.

The Permanente Medical Group, a growing multispecialty group, is recruiting physicians in a variety of specialties for positions throughout our beautiful Northern California region: the San Francisco Bay Area, Sacramento and the Central Valley.

Obstetrician/Gynecologist

Seeking a BC/BE Obstetrician/Gynecologist to provide outpatient care in our Pleasanton medical office building and inpatient care at the Kaiser Hospital/Walnut Creek. Position involves supervision of NPs. Academic affiliation available. Enjoy easy access to the recreational and cultural activities of the San Francisco Bay area. We offer competitive salary and an excellent benefits package including full coverage malpractice insurance, medical, dental and group life insurance, vacation, educational leave and an excellent retirement program.

For more information, send CV to: Patrick Golden, M.D., The Permanente Medical Group, Inc., 5600 Stoneridge Mall Road, Pleasanton, CA 94588. EOE

KAISER PERMANENTE
Good People. Good Medicine.

OB/GYN—BC/BE for large established northeastern fee-for-service multispecialty group to join active 3 member Department of OB-GYN. Beautiful suburban NYC setting and academic affiliation with one of NY's finest medical schools. Excellent salary leading to partnership. Position for July 1991 or sooner. Send CV to P.O. Box 731 Summit, NJ 07902-0731.

Full Time Faculty Positions

The Department of OB/GYN at Temple University Health Science Center is seeking Board Certified or Board Eligible Obstetrician/Gynecologists in the following areas:

MATERNAL-FETAL MEDICINE
GYNECOLOGIC ONCOLOGY
REPRODUCTIVE ENDOCRINOLOGY
GENERAL OBSTETRICS & GYNECOLOGY

Clinical and academic activities are integrated in a department providing tertiary services. Newly opened Temple University Hospital houses a modern Labor and Delivery Suite and large Neonatal Intensive Care Unit. Candidates should have an active interest in Research, Clinical Practice and Resident and Medical Student Education. Salary and academic rank commensurate with experience. Submit C.V. to: **E. Albert Reece, M.D., Chairman, Dept. of OB/GYN, TEMPLE UNIVERSITY HEALTH SCIENCE CENTER, Broad & Ontario Sts., Philadelphia, PA 19140.** Equal Opportunity Employer.

TEMPLE

OB/GYN CHIEF

The Department of Gynecology and Obstetrics at The Union Memorial Hospital is currently accepting applications for the position of Chief of Gynecology and Obstetrics and director of a fully accredited residency training program. Union Memorial is a 350 bed teaching hospital in Baltimore, Maryland. Applicants must be board certified in OB/GYN with subspecialty boards preferred, have administrative, clinical, teaching, and research experience. For confidential consideration, please send CV to:

Marcella Roenneburg, M.D.
The Union Memorial Hospital
201 E. University Parkway
Baltimore, Maryland 21218

UNIVERSITY OF DUNDEE
Department of Obstetrics and Gynaecology

PART-TIME CLINICAL SENIOR LECTURER

The holder of this post will undertake some of the clinical responsibilities of Professor P W Howie while he is Dean of the Faculty of Medicine and Dentistry. Applicants should be experienced in Obstetrics and Gynaecology and must hold the MRCOG or equivalent qualification. The successful applicant will be awarded 50% of a clinical lecturer's salary (£31,780 per annum) and will be free to undertake research in the remainder of his/her time. The post would be ideal for someone wishing to undertake sabbatical leave and able to provide the balance of his/her salary from alternative sources; the appointment would be ideally for a two-year period although applications for a one-year appointment would also be considered. Applicants must be eligible for full registration with the GMC in order to qualify for an associated Honorary Consultant Contract.

The Department of Obstetrics and Gynaecology is part of the Centre for Human Development Research at Ninewells Hospital and Medical School, Dundee, and has an active research programme in perinatal medicine running a successful in-vitro fertilisation research unit.

Further particulars from, and applications in writing with CV and the names and addresses of three referees as soon as possible to:

The Personnel Office,
The University,
Dundee,
DDI 4HN
Scotland.

norethindrone/ethinyl estradiol

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28 day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

CONTRAINDICATIONS: Oral contraceptives should not be used in women who currently have the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Carcinoma of the endometrium or other known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice with prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, and gallbladder disease, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this brief summary is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this brief summary epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease, namely a *ratio* of the incidence of a disease among oral contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods. 1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. a. Myocardial Infarction. An increased risk of myocardial infarction has been associated with oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers, especially in those 35 years of age and older among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in WARNINGS). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors. b. Thromboembolism. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease associated with oral contraceptives is not related to length of use and disappears after pill use is stopped. A two- to four-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate postpartum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four weeks after delivery in women who elect not to breast feed. c. Cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users, for both types of strokes, and smoking interacted to increase the risk of stroke. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for nonsmokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women. d. Dose-related risk of vascular disease from oral contraceptives. A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the activity of the progestogen used in the contraceptive. The activity and amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing 0.035 mg or less of estrogen. e. Persistence of risk of vascular disease. There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral contraceptive formulations containing 50 micrograms or higher of estrogens. 2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE. One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who use oral contraceptives have a significant increase in mortality higher than those using other methods of birth control. These facts must be weighed in conjunction with failure rates for other methods and the risk associated with subsequent pregnancy. 3. CARCINOMA OF THE REPRODUCTIVE ORGANS. Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. While there are conflicting reports most studies suggest that use of oral contraceptives is not associated with an overall increase in the risk of developing breast cancer. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use. Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. 4. HEPATIC NEOPLASIA. Benign hepatic adenomas are associated with oral contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use especially with oral contraceptives of higher dose. Rupture of benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users approaches less than one per million users. 5. OCULAR LESIONS. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia, papilledema, or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately. 6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. The majority of recent studies also do not indicate a teratogenic effect, particularly in so far as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued until pregnancy is ruled out. 7. GALLBLADDER DISEASE. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens. 8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. This effect has been shown to be directly related to estrogen dose. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects prediabetic and diabetic women in particular should be carefully monitored while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see WARNINGS 1a and 1d), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users. 9. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in women taking oral contraceptives, and this increase is more likely in older oral contraceptive users and with extended duration of use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing progestational activity. Women with a history of hypertension or hypertension-related diseases, or renal disease, should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension between former and never users. 10. HEADACHE. The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause. 11. BLEEDING IRREGULARITIES. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent. 12. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. **PRECAUTIONS:** 1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine and liver function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3, increased norepinephrine-induced platelet aggregability. b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radio-immunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See WARNINGS section. 10. PREGNANCY. Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS. Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child. **INFORMATION FOR THE PATIENT: See Patient Package Insert. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS section). Thrombophlebitis and venous thrombosis with or without embolism. Arterial thromboembolism. Pulmonary embolism. Myocardial infarction. Cerebral hemorrhage. Cerebral thrombosis. Hypertension. Gallbladder disease. Hepatic adenomas or benign liver tumors. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea. Vomiting. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Amenorrhea. Temporary infertility after discontinuation of treatment. Edema. Melasma which may persist. Breast changes: tenderness, enlargement, secretion. Change in weight (increase or decrease). Change in cervical erosion and secretion. Diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome. Cataracts. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. Acne. Changes in libido. Colitis. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea and withdrawal bleeding may occur in females.

Introductory remarks

Robert B. Jaffe, MD, and Samuel S. C. Yen, MD, DSc

San Francisco and La Jolla, California

In recent years, there has been a remarkable expansion of our understanding of endocrinologic events and in the translation of this basic understanding into the clinical arena. A seminal observation in reproductive neuroendocrinology was made in 1970 by Knobil et al.,[1] who reported on the oscillatory fluctuations in luteinizing hormone (LH) concentration in the plasma of ovariectomized monkeys. Now, 20 years later, this observation has led to the introduction of pulsatile gonadotropin-releasing hormone (GnRH) and to the development of agonistic and antagonistic analogs of GnRH to treat a variety of endocrinologic disorders.

During the intervening 20 years, many of the complex mechanisms involved in the neuroendocrinologic control of gonadotropin secretion were gradually and elegantly revealed. The physiologic importance of the pulsatile nature of gonadotropin secretion was demonstrated in 1978, when Belchetz et al.[2] reported that only pulsatile and not continuous administration of exogenous GnRH could reestablish gonadotropin secretion in monkeys deprived of endogenous GnRH by radiofrequency lesioning the arcuate nucleus of the hypothalamus, the site of most GnRH production. Moreover, the frequency of pulsatile GnRH administration was critical. In monkeys the ideal frequency was 60 minutes[3]; however, recent studies in humans have shown that frequencies of 60 to 120 minutes are effective in restoring normal gonadotropin secretory patterns.

Most of the early investigations into the neuroendocrinology of gonadotropin secretion and regulation were carried out in experimental animal systems. Nature, however, has provided its own set of experimental models. The disorders of gonadotropin secretion for which pulsatile GnRH may provide an ideal treatment, such as hypothalamic amenorrhea, also provide investigators with ideal systems in which to study the regulatory mechanisms involved in GnRH function.

Hypothalamic amenorrhea can result from a number of physiologic and environmental conditions. However, the common features in persons with this disorder are intact pituitary-ovarian-endometrial function and a deficiency in the pulsatile secretion of GnRH. The neuroendocrinologic basis for this deficiency is not definitely known; these women provide a useful model for the study of the regulatory mechanisms involved in normal gonadotropic function. From a clinical standpoint, these women are anovulatory, and many of them desire pregnancy. Because the pituitary-ovarian axis is operative in these women, GnRH, when presented in a physiologic, pulsatile manner, can be quite effective in inducing ovulation and ultimately pregnancy.

Although the cause of polycystic ovary syndrome is quite distinct from that of hypothalamic amenorrhea, the clinical concerns may be similar. Anovulation is common in these women, and ovulation induction is often necessary to treat infertility. Since existing methods of ovulation induction are frequently ineffective, more effective means of induction would be desirable. Pulsatile GnRH alone has not been very effective in inducing ovulation in this disorder. However, the use of a GnRH analog to create a hypogonadotropic state before the administration of pulsatile GnRH shows great promise as a treatment for anovulation in women with polycystic ovary syndrome.

Disorders of GnRH pulse generation have also been identified in men. In idiopathic hypogonadotropic hypogonadism, LH secretion is usually apulsatile, an observation that suggests the absence or severe reduction of GnRH pulse generation. Treatment of idiopathic hypogonadotropic hypogonadism with testosterone therapy is usually sufficient to promote pubertal development and normal sexual function. In patients in whom induction of sperm production and fertility are desired, long-term therapy with pulsatile GnRH has proved quite successful in experimental studies. With

6/0/24912

the availability of GnRH for clinical use, replacement therapy for men with idiopathic hypogonadotropic hypogonadism should now become a real option.

This symposium integrates the basic research into the physiologic principles of GnRH pulse generation and the clinical applications to which this basic research has so logically led. The clinical disorders that will be discussed result from a defect in the pulsatile secretion of GnRH by the hypothalamus. The use of pulsatile GnRH in the treatment of these disorders is inherently attractive because it is a physiologic means of correcting a physiologic defect.

The notion of an oscillator or signal generator in the central nervous system that controls the rhythmic release of GnRH and, thereby, the pulsatile secretion of the gonadotropic hormones, originated in the finding of strikingly abrupt and rhythmic fluctuations in the concentration of LH in the plasma of ovariectomized monkeys. These oscillations had a period of about one hour when blood samples were obtained at 10 to 20 minute intervals.[1]

These surprising observations were presaged by reports of seemingly random, major fluctuations in plasma gonadotropin concentrations in gonadectomized monkeys[2] and rats[3, 4] as well as in women.[5] In these earlier studies the sampling intervals employed were never less than one hour and unable, therefore, to reveal the orderly, rhythmic events that occur with frequencies of one event per hour, or more.

In the original study describing pulsatile LH secretion in ovariectomized monkeys the possibility was considered that the circhoral discharges of LH may be initiated by autoregulatory mechanisms involving long or short feedback loops, but the more likely view that these discharges were due to intermittent signals from the central nervous system unrelated to circulating LH levels that resulted in putative increments in GnRH release was favored. Nevertheless, the possible role of autoregulatory mechanisms in the control of pulsatile LH secretion was repeatedly considered,[6] but finally laid to rest in the relatively recent past.[7] Conversely, the view that each pulse of LH released from the pituitary gland is the consequence of a bolus of GnRH secreted into the pituitary portal system has been unequivocally upheld by the demonstration of synchronous increments of GnRH assessed in the pituitary portal circulation and of LH measured in samples of peripheral blood obtained simultaneously.[8, 9] In any case, the phenomenon of pulsatile gonadotropic hormone secretion was rapidly extended to most vertebrate species studied in this regard, including our own, and forms the basis of an increasingly voluminous, rapidly expanding literature.

In the monkey[10] as in the rat[11] total surgical deafferentation of the mediobasal hypothalamus does not interfere with pulsatile gonadotropic hormone secretion suggesting that what has become known as the GnRH pulse generator lies within this structure. Somewhat more precise localization was achieved in the rhesus monkey by the demonstration that bilateral destruction of the area comprising the arcuate nuclei promptly abolished gonadotropin secretion without notable effects on the production of the other adeno- and neurohypophysial hormones.[12] That the GnRH pulse generator is an intrinsic property of the medial basal hypothalamus has been affirmed by the demonstration of pulsatile GnRH release at appropriate frequencies from superfused hypothalamic fragments in vitro.[13]

The physiologic significance of the pulsatile mode of gonadotropin secretion became apparent with the finding that gonadotropin secretion could be reestablished in rhesus monkeys deprived of endogenous GnRH secretion by destruction of the arcuate nucluei only by the intermittent administration of exogenous GnRH at the physiologic frequency of one pulse per hour, continuous infusion of the decapeptide provoking but an evanescent response followed by desensitization of the gonadotrophs.[14, 15] In fact, the administration of GnRH at an unvarying frequency of one pulse per hour to such animals supported normal, ovulatory menstrual cycles affirming the conclusion[14] that, in this species, hypothalamic GnRH secretion is a permissive component of the ovarian cycle rather than its controller.[16] More to the point, the pulsatile administration of GnRH to prepubertal female monkeys promptly established normal ovarian function including 28-day ovulatory menstrual cycles.[17] These findings demonstrated that nothing below the hypothalamus was limiting in the advent of puberty and suggested that the pubertal process may be initiated by an activation of the hypothalamic GnRH pulse generator. This fundamental issue is discussed at length by other contributors to this symposium and will not be reconsidered here.

The central importance of the GnRH pulse generator as a limiting component of the control system that governs reproductive processes has been widely documented in a number of species including man (see 18, 19, 20, 21 for review). Much of what is known about

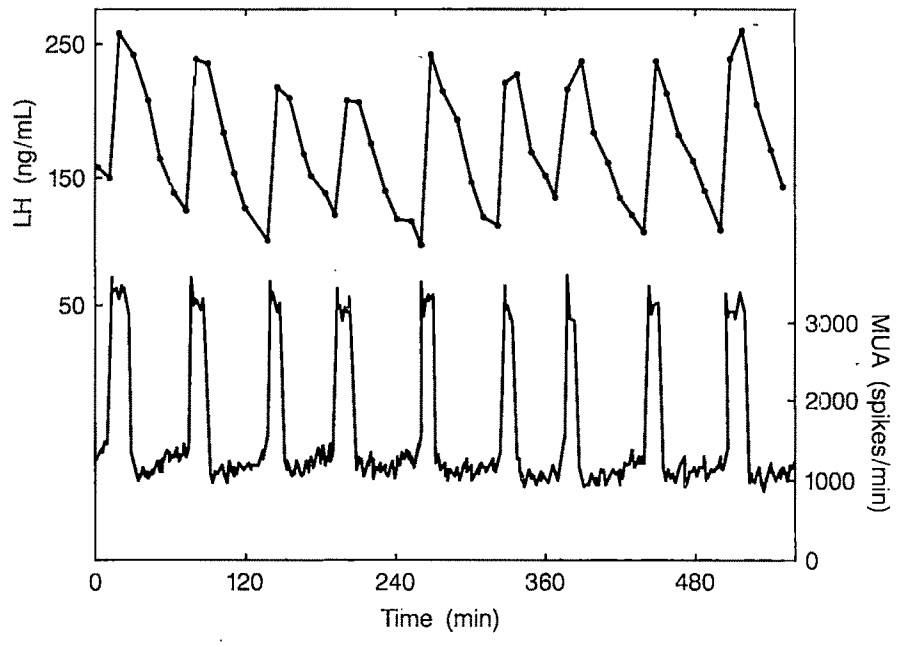

Fig. 1. Characteristic volleys of electrical activity *(MUA)* recorded from the medial basal hypothalamus in relation to LH pulses in the peripheral circulation in an ovariectomized monkey.

the operation of this neuronal system is based on the monitoring of LH pulses in the peripheral circulation. While such pulses may provide an unambiguous reflection of the pulsatile discharges of GnRH into the pituitary portal circulation in some circumstances, notably when negative feedback loops are open and experimental influences directly on pituitary function have been eliminated, this approach has clear limitations. In the presence of the gonads, the magnitude of the LH pulses is much reduced and requires rigorous statistical techniques for their identification[22] and even these do not always eliminate uncertainty. More importantly, the operation of the pulse generator cannot be monitored by this approach in the complete absence of LH pulses attributable to blockade of LH release at the pituitary level.

While, at the moment, there are no alternatives to this approach in human subjects, more direct assessments of GnRH pulse generator activity have been attempted in experimental animal preparations. In addition to the measurement of GnRH in pituitary portal blood and in the superfusion medium from isolated hypothalamic preparations *in vitro* already mentioned, these have included the measurement of GnRH in hypothalamic extracellular fluid using the "push-pull" technique[23, 24, 25] or in cerebrospinal fluid sampled from the third ventricle.[26]

Over a decade ago our own laboratory initiated an alternative, direct approach to the GnRH pulse generator based on the supposition that the discharge of GnRH from the terminals of GnRH cells must be a consequence of action potentials as demonstrated in a variety of other neurosecretory systems. We further reasoned that the intermittent release of GnRH in physiologically effective quantities must reflect the simultaneous discharge of a number of GnRH cells and that the antecedent, synchronous electrical events should be measurable using multiunit recording techniques as demonstrated for the magnocellular component of the hypothalamus in the rhesus monkey and other species. We thus applied the techniques devised by Hayward and his associates[27] for measuring the multiunit electrical activity (MUA) generated by vasopressin cells responding to appropriate osmotic stimuli to the search for the GnRH pulse generator of the rhesus monkey. Our strategy was based on the fact that we knew where to place the recording electrodes (in the region of the arcuate nucleus) and on the availability of unambiguous points of reference provided by the circhoral LH pulses seen in ovariectomized animals. While early results[28] were encouraging and prompted us to continue the search, successful outcomes occurring with acceptable frequency were not obtained until we switched from single, acutely placed electrodes to permanently implanted bilateral arrays of multiple electrodes that essentially blanketed the entire medial basal hypothalamus.[29] Dramatic increments in MUA coincident with the initiation of LH pulses, as measured in the periphery, could then be demonstrated with reasonable reproducibility (Figure 1). Because barbiturate anesthesia does not abolish the pulsatile secretion of LH in the rhesus monkey,[30] such results were initially obtained in animals anesthetized with pentobarbital to reduce electrical noise associated with muscular movement and

to minimize unrelated central electrical activity. It was found subsequently that the MUA discharges associated with LH pulses ("volleys" of electrical activity, as we have come to call them) were demonstrable with equal clarity in awake ovariectomized monkeys restrained in primate chairs.[29]

These MUA volleys were so striking that we initially suspected them to be artifactual despite their invariable coincidence with LH pulses, but only because we had expected, when we began the attempt, that the likelihood of success was vanishingly small and that, if we were to see anything at all, it would be subtle and difficult to discern without the assistance of statistical manipulation designed to distinguish pulse generator signals from ambient neuronal electrical activity. We were eventually reassured that we were indeed monitoring the activity of the GnRH pulse generator by the outcome of a series of pharmacological interventions previously shown to modify the frequency of LH pulses in the ovariectomized rhesus monkey (see below). In all of them, every alteration in LH pulse frequency was mirrored in simultaneous changes in MUA volleys. To date, in literally thousands of observations, every MUA volley observed has been followed by an LH pulse. The converse, of course, does not obtain. In animals that have regular LH pulses but no concomitant changes in electrical activity, the electrodes simply have missed their mark and electrode reimplantation usually yields a useful preparation.

In general, the hypothalamic structures from which the successful recordings have been made grossly coincide with the GnRH neuronal system of the rhesus monkey previously identified by immunocytochemical techniques.[31] Whether the recordings are made from GnRH cells or fibers or from cells or fibers that do not contain GnRH could not be ascertained because of the relatively large diameter (50 μm) of the recording electrodes relative to these structures.[31]

The pharmacological studies already alluded to, beyond validating the specificity of our electrophysiological observations, have also provided some insight relevant to the operation of the GnRH pulse generator but not sufficiently so to permit the construction of compelling models. Barbiturates slow the frequency of the system in dose-dependent fashion[29, 32] as does prolonged treatment with ketamine. Alpha-adrenergic and dopaminergic blockade also reduces the frequency of MUA volleys and of the consequent LH pulses.[33] Similarily, morphine dramatically interrupts the firing of the pulse generator, an action blocked by naloxone, while naloxone alone, at the doses given was without effect in these ovariectomized animals,[34] suggesting minimal opiate tone in the absence of the gonads.

Because *N*-methyl D-aspartic acid (NMDA) is a potent stimulator of the LH release in the rhesus monkey[35, 36] the role of NMDA receptors in the operation of the GnRH pulse generator was investigated. Our preliminary findings to date indicate that NMDA administration to ovariectomized monkeys indeed elicits MUA volleys followed by LH pulses. NMDA receptor blockade with AP-5, administered intracerebrally, appears to have a range of dose-independent effects on pulse generator activity, from prolonged arrest to minor delays of the MUA volleys that immediately follow the injection of the drug.[37] The most dramatic effects of the blocker were associated with profound behavioral disturbances and could, therefore, have been due to non-specific actions of the drug. The non-competitive inhibitor MK 801, while inducing anesthesia was, in a single animal, without effect on pulse generator activity.[37]

Because the frequency of LH pulses (circhoral) has been reported to be essentially the same during the follicular phase of the menstrual cycle, when estrogen levels are maximal, and in the absence of ovarian function, when they are immeasurable, it was concluded that estradiol in physiological concentrations does not have a significant effect on pulse generator frequency.[21] We were surprised to find, therefore, that physiological estrogen replacement in ovariectomized monkeys profoundly inhibited pulse generator activity.[38] The reason for this difference between intact and ovariectomized monkeys remains to be resolved but the finding is reminiscent of earlier observations showing remarkable differences in the apparent steroidal control of gonadotropin secretion between ovariectomized and normal animals.[39] It was noted in passing that the reduction in pulse generator frequency in ovariectomized monkeys occasioned by physiological levels of estradiol was accompanied by a decrease in the *duration* of individual MUA volleys.[38] The control of volley duration, in contradistinction to pulse generator frequency, and its significance are discussed further below.

Our purpose from the outset of our electrophysiological efforts was to study the function of the GnRH pulse generator throughout the menstrual cycle of the rhesus monkey and in other physiological settings such as the initiation of puberty. Such investigations, obviously, can only be conducted in intact animals. While all of the foregoing work in ovariectomized monkeys was being conducted, attempts to study the pulse generator in normal animals were unrelentingly pursued but without success. In the original observations of LH pulses in ovariectomized monkeys it was noted that these could not be seen in intact females.[1] It was supposed at the time, and not entirely incorrectly in retrospect, that in the presence of the ovaries and a closed negative feedback loop, the LH pulses were too small to be detected by our radioimmunoassay. It was discovered nearly 20 years later, however, when an ex-

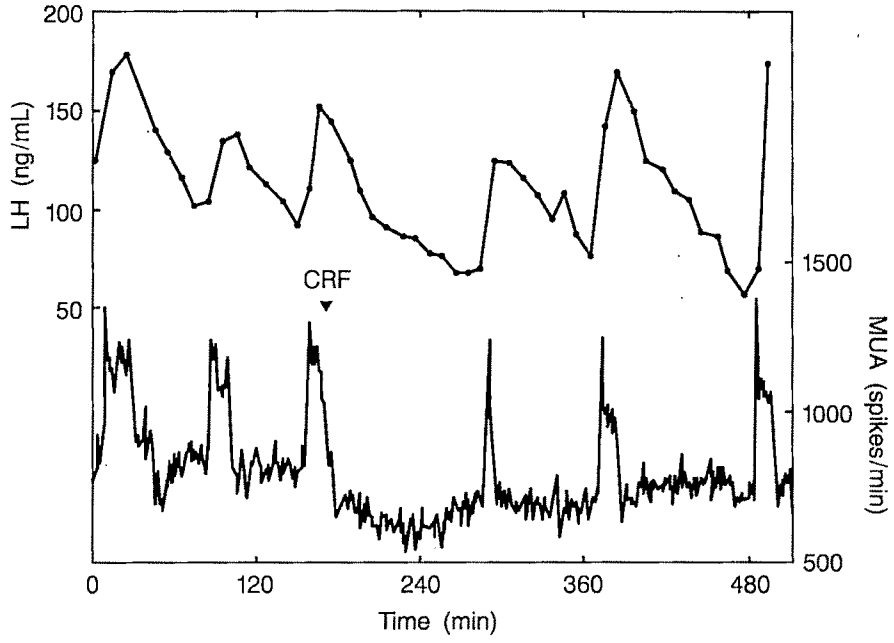

Fig. 2. Effect of a single intravenous injection of corticotropin-releasing factor *(CRF)*, at *arrow*, on GnRH pulse generator activity in an ovariectomized rhesus monkey.[12]

tremely sensitive bioassay was substituted for the immunoassay, that LH pulses still could not be detected in normal monkeys restrained in primate chairs. We gradually came to the realization that the mild "stress" of chair restraint, to which the animals appeared to be accustomed, had arrested the GnRH pulse generator. Blood samples taken from intact animals under barbiturate anesthesia or otherwise tranquilized did show clear LH pulses, as well as the attendant MUA volleys, albeit at a reduced frequency. Michel Ferin and his colleagues had also noted that chair restraint interferes with pulsatile LH secretion in intact monkeys and that this could not be reversed by naloxone administration.[10] We have found, as they did, that corticotropin releasing hormone (CRH) inhibits pulsatile LH secretion, and that the effect of the neuropeptide could occasionally be reversed by naloxone[11, 12] but the relationship between these observations and the consequences of stress remain to be clarified. An example of this phenomenon is shown in Figure 2. In any case, the remarkable difference between ovariectomized and intact monkeys in the resistence of the GnRH pulse generator to stress presents a problem of fundamental importance.

Intact rhesus monkeys, fitted with recording electrodes and chronic indwelling cardiac catheters do exhibit normal, ovulatory menstrual cycles and must, therefore have a normally functioning hypothalamic GnRH pulse generator when they are not subject to the brief periods of restraint in primate chairs. Although pulse generator activity in such animals was easily demonstrable when CNS depressants were given, thus bypassing chair restraint, this obviously did not provide a satisfactory approach to the study of normal hypothalamic function and an alternative strategy had to be devised. For this purpose, we developed a radiotelemetry system composed of a radiotransmitter to which the distal end of a recording electrode is attached, a receiving antenna placed in close proximity to a suitably modified cage and an ordinary FM receiver.[13] The hypothalamic signals are then processed in a manner identical to the "hard wired" system previously described.[29] This technique permits continuous recording of MUA activity in unrestrained animals for unlimited periods of time. More recently, we have found that intensive habituation of normal monkeys to primate chair restraint, for extended periods, reestablishes normal GnRH pulse generator activity and provides the opportunity to study the system in the presence of the ovaries, at least for the limited time offered by a single experimental day, the maximum period of restraint that we have employed.

These rather arduous methodologies, developed over a period of years, are only now beginning to provide reliable descriptions of the function of the GnRH pulse generator in the normal rhesus monkey. Among these is the confirmation of earlier findings in the human and monkey (see 21 for review) that pulse generator frequency is markedly reduced during the luteal phase of the cycle as well as during the night, especially during the follicular phase of the cycle, suggesting an interaction between circadian timing mechanisms and the circhoral signal generator of the hypothalamus.

Totally unexpected, however, was the finding, to be published in detail elsewhere, of an abrupt reduction

in the frequency of the pulse generator coincident with the preovulatory, mid-cycle LH surge. Again, this is accompanied by concurrent reductions in LH pulse frequency.

Another unanticipated observation was the marked difference in the duration of MUA volleys between normal and ovariectomized animals. The period of increased electrical activity of the GnRH pulse generator lasts for five minutes, on the average, in normal monkeys during the follicular phase of the cycle in contrast to about 20 minutes in ovariectomized animals.[14] As already mentioned, estradiol administered to ovariectomized animals seemed to shorten the duration of MUA volleys as well as reduce the frequency of the pulse generator. In a more recent study it has been found that while naloxone blocks the effect of estradiol on pulse generator frequency, it has no effect on the action of the steroid on MUA volley duration. Morphine, however, mimics the actions of estradiol, but when administered at an appropriate rate, can reduce volley duration without significant effect on frequency.[14] Taken together, these observations suggest that frequency and duration of activation of the GnRH pulse generator can be controlled independently. Because the duration of MUA volleys is unrelated to the amount of LH released per pulse it appears that the full complement of GnRH released by each activation of the pulse generator is discharged at the onset of electrical activity.[15] While control of MUA volley duration may be of little moment in terms of LH secretion, it may provide potentially important insights regarding the functioning of the pulse generator at the cellular level.

Despite the contemplation of the GnRH pulse generator in terms of its outputs for two decades, the relentless probing of its workings with pharmacological tools and the deciphering of its electrophysiological substrate, we remain woefully ignorant of the neuronal construct that underlies its activity. That the pulse generator is an intrinsic property of the MBH, probably of the arcuate nucleus, seems reasonably certain. In the monkey and human it has a frequency of approximately one pulse per hour in its unmodulated (open loop) state and this frequency is maximal or close to it. The elementary question of whether the pulse generator resides in GnRH neurons or in cells that eventually synapse with them remains to be definitively answered.

The simplest hypothesis is that a single pacemaker cell, or small group of cells, initiates each pulse and entrains all other participants in the consequent neuroendocrine cascade, thus accounting for the mandatory synchrony of GnRH release. But the circhoral frequency of such pacemaker neurons, if they exist, is difficult to explain in terms of currently understood neurocellular control systems. The finding, however, that the pacemaker for the circadian rhythm of the marine snail *Bulla* resides in a small cluster of cells at the base of its eyestalks, and that only one of these cells may be capable of timing the entire circadian behavior pattern of this animal[16] provides a small measure of credibility to the possibility that the pacemaker for a circhoral rhythm may also reside in kindred cellular domains. But as is often the case, the simplest models are unequal to the task and more complex hypotheses may eventually have to be tested and affirmed or rejected in their turn.

Discussion

Audience. In one of your slides there seemed to be a difference at the beginning of the cycle between the follicle-stimulating hormone (FSH) and LH response to pulsatile GnRH. Do you think that the relatively greater increase in FSH than in LH levels is important in folliculogenesis?

Dr. Knobil. At present we do not know the physiologic role of the relative elevation of FSH levels at the beginning of the cycle.

Audience. Have you looked for a similar correlation between electrical spikes and other neuroendocrine hormones or neurotransmitters?

Dr. Knobil. The secretion of all the pituitary hormones, and most peptide neurotransmitters, is episodic. We looked for changes in hormone secretory patterns that are synchronous with LH and FSH, and we could not find any except prolactin, under certain circumstances. It has been found that GnRH, in appropriate circumstances, does stimulate prolactin secretion. So far we have been unable to find electrophysiologic correlates for patterns of peptide hormone secretion other than GnRH.

Neuromodulatory regulation of gonadotropin-releasing hormone pulsatile discharge in women

Robert B. Jaffe, MD, Shayne Plosker, MD, Lorna Marshall, MD, and Mary C. Martin, MD
San Francisco, California

The pulsatile release of gonadotropin-releasing hormone and the consequent secretion of gonadotropins are regulated by a complex interplay of steroids, neuropeptides, catecholamines, and environmental factors. Estrogen and progesterone influence the amplitude and frequency of luteinizing hormone pulsatile secretion. These effects lead to both a diurnal variation in pulse frequency, with a lower frequency at night, and variation during the menstrual cycle, with a lower frequency and increased amplitude during the luteal phase. Opioid peptides inhibit the pulsatile discharge of gonadotropin-releasing hormone and luteinizing hormone. The opioid antagonist, naloxone, causes an increase in luteinizing hormone secretion, particularly during the luteal phase. The administration of opioid receptor agonists, such as β-endorphin, results in a decline in serum luteinizing hormone during the early follicular phase. Corticotropin-releasing factor, which is increased during stress, inhibits pulsatile luteinizing hormone secretion, and this effect can be blocked by the simultaneous administration of naloxone. These observations suggest that corticotropin-releasing factor exerts its effects on luteinizing hormone through an opioidergic intermediary. Endogenous catecholamines such as dopamine inhibit pulsatile luteinizing hormone release; however, the mechanism involved is not clear. (Am J Obstet Gynecol 1990;163:1727-31.)

Key words: Gonadotropin-releasing hormone, catecholamines, opioids, steroids

Pulsatile discharge of gonadotropins, and thus of gonadotropin-releasing hormone (GnRH), has its origins in intrauterine life. Rasmussen et al.[1] have demonstrated pulsatile release of GnRH from the human fetal pituitary superfused in vitro. In vivo Martin et al.[2] have demonstrated pulsatile release of luteinizing hormone (LH) in the catheterized rhesus monkey fetus in utero. This pulsatile release was evident by at least 130 days' gestation (term = 165 days). The amplitude of LH pulses was greater in female than in male fetuses, presumably because of the restraining action of testicular testosterone in the male. Near term pulsatile LH discharge was markedly diminished in both sexes.

In 1971 Midgley and Jaffe[3] and Yen et al.[4] demonstrated that the episodic release of LH in women varied in amplitude and frequency at different stages of the cycle. Pulses of high frequency and low amplitude were observed during the follicular phase of the cycle, whereas pulses of high amplitude and relatively lower

6/0/25004

frequency were observed during the luteal phase. More recently Soules et al.[5] and Marshall et al.[6] demonstrated a nocturnal slowing of LH pulses in women during the follicular phase. Soules et al. did not find this pattern during the late follicular or midluteal phase. All these observations suggest an influence of estrogens and progesterone on the magnitude and frequency of pulsatile LH discharge. Marshall et al. also demonstrated that effecting preovulatory circulating concentrations of estradiol caused a diurnal change in LH pulse discharge. In addition, this concentration of estradiol inhibited LH pulse discharge for the first 3 to 5 hours after sleep. The diurnal pulsatile discharge of LH, which was brought about by the peak preovulatory concentrations of estradiol, occurred with a nadir of mean LH concentrations at 1000 to 3000 hours and an acrophase at 800 to 1000 hours. Because the midcycle LH surge in serum usually occurs during the early mornings, these investigators suggested that the critical concentrations of estradiol might be responsible for this phenomenon.

Jaffe and Keye[7] demonstrated previously that estradiol sensitizes the pituitary to GnRH. It is also likely that this phenomenon contributes to the initiation of the midcycle LH surge. Dumesic et al.[8] demonstrated that this estradiol sensitization of the pituitary gland to GnRH has its origins during intrauterine fetal life. Thus a large number of studies, including those noted above, indicate that the steroid milieu of the hypothalamic-pituitary system plays a critical role in the nature of GnRH and gonadotropin pulsatile discharge.

Opioids

The opioid peptides, particularly β-endorphin, inhibit pulsatile discharge of GnRH and LH. Opioid regulation of the GnRH pulse generator is probably central to the control of pulsatile discharge. Wardlaw et al.[9] demonstrated that long-term administration of estradiol plus progesterone markedly increased the concentration of β-endorphin in the hypothalamic-pituitary portal circulation of rhesus monkeys. The opiate antagonist, naloxone, causes an increase in pulsatile discharge of LH in women during the menstrual cycle that is greatest during the luteal phase of the cycle.[10] Morphine administration to castrate monkeys also inhibited pulsatile LH release, and this effect could be blocked by the administration of naloxone.[11] Thus opioids inhibit pulsatile discharge of GnRH, and the extent of this inhibition during the menstrual cycle is dependent on circulating levels of estradiol and progesterone.

Rasmussen et al.[1] showed that the pulsatile discharge of GnRH from the fetal and adult hypothalamus superfused in vitro is enhanced by the simultaneous administration of naloxone, which again suggests that regulation of pulsatile discharge of GnRH has its inception during pregnancy.

Corticotropin-releasing factor, which regulates the production of pituitary adrenocorticotropic hormone and β-endorphin, is increased during stress. The administration of corticotropin-releasing factor to castrate female rhesus monkeys inhibits pulsatile LH release.[12] This effect can be obviated by simultaneous long-term infusion of naloxone. These data suggest that corticotropin-releasing factor exerts its inhibitory action on pulsatile LH release through an opioidergic intermediary. A study by Barbarino et al.[13] during the midluteal phase of the menstrual cycle suggested that a similar mechanism of opioid modulation by corticotropin-releasing factor was operative in the inhibition of pulsatile LH discharge. These phenomena may be involved in the mechanism of stress-induced amenorrhea.

The administration of opioid receptor agonists, such as β-endorphin, enkephalin analogs, and morphine, increases serum prolactin in men and women. Concurrent with the increase in prolactin, declines in serum LH have been demonstrated in women during the early follicular phase in response to β-endorphin[14] and in postmenopausal women in response to an enkephalin analog[15] but not in postmenopausal women treated with β-endorphin.[16]

The lack of response of LH to β-endorphin in postmenopausal women may indicate that gonadotropin sensitivity to opioidergic modulation is dependent on the presence of adequate amounts of gonadal steroids. However, a decline in LH in response to an enkephalin analog in postmenopausal women not receiving steroid replacement has been observed.[15] Different biologic potencies, rates of metabolism, and different experimental conditions may have contributed to the observed differences.

The decrements in circulating LH seen in humans in response to opioid receptor agonists are qualitatively similar to those in rodents and nonhuman primates. The in vivo and in vitro evidence is that opioids can regulate gonadotropin secretion by inhibition of tuberoinfundibular GnRH secretion in humans by mechanisms similar to those in rodents and nonhuman primates. This evidence is more substantive than the evidence for a parallel mechanism of interaction between opioids and dopamine.

Gonadotropin response to opioid antagonists. The picture that has emerged from opiate antagonist studies is one in which endogenous opioid substances modulate pituitary LH secretion but only under physiologic conditions characterized by sufficient quantities of gonadal steroids (i.e., in the late follicular to midluteal

phases of the menstrual cycle).[17-19] The pattern of LH responses to naloxone is consistent with tonic endogenous opioidergic inhibition of GnRH secretion.

As in other species, opioid receptor blockade in humans results in increases in LH, although in healthy women this effect is limited to estrogenic or estrogenic-progestogenic environments.[18-22]

Response in different estrogen environments. In women, ovarian estrogen secretion is low during the early follicular phase. The administration of naloxone during this phase of the menstrual cycle does not bring about a change in gonadotropin levels,[23, 24] which indicates that estradiol levels are insufficient during the midfollicular phase to induce endogenous opioid tonic modulation of gonadotropins. However, in a study during the early follicular phase, significant increments in LH were observed in response to naltrexone.[25] These findings, in contrast to those in which naloxone was used, suggest a role for tonic endogenous opioid regulation of LH secretion during the early follicular phase. Different effects of naloxone and naltrexone may be the result of differences in potency, receptor binding, or purity as an antagonist.

The role of gonadal steroids in regulating endogenous opioid tone becomes apparent in the high estradiol environment of the late follicular phase. When naloxone was infused in the late follicular phase 3 days before the anticipated LH surge, half of the women had marked increases in LH pulse amplitude that resembled a spontaneous LH surge. The surge lasted 24 hours, and postsurge ovulation occurred. The other women did not respond. The group of nonresponders had estradiol levels significantly lower during naloxone infusion than on the day before the spontaneous surge in the antecedent control cycle. This suggests an obligatory role for estradiol in the regulation of endogenous opioid tone at this time of the cycle.[19] Because the characteristics of the LH surge in those women who responded to naloxone were similar to the characteristics of physiologic spontaneous LH surges, this study provides evidence that the initiation of the LH surge may be mediated by physiologic withdrawal of endogenous opioid tone in the presence of sufficient quantities of estradiol.

In the high estradiol-progesterone environment of the midluteal phase, naloxone administration was associated with increased LH pulse frequency.

Long-term opioid antagonism with naltrexone that was administered during the first week of the luteal phase produced subtle effects on LH. There was an increase in midluteal LH pulse frequency, but total LH secretion did not increase.[18] The less dramatic effects seen with long-term opioid antagonism compared with short-term naloxone infusion studies may reflect an ability of the central nervous system–GnRH-pituitary-ovarian axis to adapt to long-term opioid withdrawal.

The administration of conjugated estrogens to previously untreated postmenopausal women brought about a return of prolactin sensitivity to opioid receptor blockade. Estrogen therapy was then discontinued, and combined estrogen-progestin therapy was started 20 days later. After 20 days on the combination regimen, infusion of naloxone resulted in prolactin elevations to 245% above baseline levels. This was a significantly greater increment than that seen with estrogen replacement in the absence of a progestin.[21] Treatment of oophorectomized women with estrogen restores opioid activity.[26] Petraglia et al.[27] showed that both fertile and climacteric women had no LH response to naloxone by 1 week after ovariectomy. The combination of conjugated estrogens and progestins restored naloxone induction of the LH rise. These findings demonstrate that estrogen and progesterone together modulate endogenous opioid tone to a greater extent than either steroid alone.

Modulators of endogenous opioid tone

Dopamine. There is evidence that dopamine modulates endogenous opioid tone, raising the possibility of a feedback loop between hypothalamic opioids and catecholamines. Dopamine receptor antagonists increase levels of β-endorphin in the hypothalamus, pituitary, and peripheral serum of rodents.[28, 29] Naloxone studies also suggest that dopamine antagonism results in increases in endogenous opiate tone. In postmenopausal women experiencing vasomotor symptoms, treatment with the dopamine receptor antagonist, veralipride, brought about a decrease in basal LH levels[30] and a reduction in core temperature that is a characteristic effect of opioids.[31] Naloxone infusion after veralipride resulted in a rise in LH levels.[30] Naloxone infusion after veralipride resulted in a rise in levels in LH.[30] These findings suggested that long-term dopamine receptor blockade resulted in elevated endogenous opioid levels, which in turn decreased LH and increased response to naloxone.

The infusion of dopamine to women during the follicular phase of the menstrual cycle in concentrations that elevated peripheral dopamine concentrations only slightly above the physiologic range did not result in significant alterations in pulsatile LH discharge.[32]

With the use of higher pharmacologic doses, suppression of LH was observed that was particularly marked in the luteal phase of the cycle.[33] Recently Plosker et al.[34] administered the tyrosine hydroxylase inhibitor, α-methyl paratyrosine, to women during the follicular phase. This inhibited endogenous catecholamine synthesis and resulted in an increase in the

amplitude of LH pulses. Thus endogenous catecholamines, primarily dopamine, appear to inhibit pulsatile LH release. It is unknown whether this action occurs in the pituitary gland or the hypothalamic GnRH pulse generator directly, or if it is mediated by hypothalamic opioids. The study by Plosker et al. suggests a hypothalamic locus of action.

Steroids The observations from experiments with naloxone and naltrexone in reproductive-age women during different intervals in the menstrual cycle and in menopausal women given pharmacologic steroid replacement imply a significant role for gonadal steroids in the modulation of endogenous opioid tone. Research on rodents and nonhuman primates has further defined this role. Steroid hormone receptors are widespread in the central nervous system, including regions of the hypothalamus, where opioid peptides, GnRH, and catecholaminergic neurons are localized.[35, 36] The neuroanatomic relationships for estrogens, progesterone, and androgens to modulate opioid-catecholamine or GnRH regulation of pituitary hormone secretion exist. Factors, such as the dose of steroid administered, the multiple sites of action of steroids,[37] the cyclic fluctuations in steroid secretion, and the interactions between steroids, often make it difficult to interpret steroidal effect.

Ovarian sex steroids appear essential for the release of β-endorphin into pituitary stalk blood, with the greater amounts of β-endorphin released in the presence of both estrogen and progesterone.[9] Also, opioid peptides probably have a role in mediating gonadal steroid feedback at the hypothalamic level. Some investigators have postulated that an alteration in opioid peptides, which are modulated by sex steroids, may be responsible for the cyclic nature of the menstrual cycle.[38-40]

Concentrations of β-endorphin in the peripheral circulation are extremely low, and hypothalamic β-endorphin activity is better reflected by direct measurements of the hormone in pituitary stalk blood. Pituitary stalk β-endorphin concentration in monkeys is high in the mid- to late follicular phase, higher in the luteal phase, and undetectable after ovariectomy or during menstruation.[41] Long-term estrogen administration to ovariectomized monkeys restored β-endorphin secretion, and the addition of progesterone further elevated β-endorphin levels.[9] In nonhuman primates ovarian sex steroids are necessary for the release of hypothalamic β-endorphin into the pituitary portal circulation.

The presence of exogenous gonadal steroids is not sufficient to activate the opioidergic control of LH secretion. A functional hypothalamic GnRH-pituitary-gonadal system from spontaneous pubertal development also seems to be necessary. The administration of an estrogen-progestin combination to patients with Turner's syndrome did not affect their response to naloxone.[42]

Gonadotropin responses to naloxone infusions in low estrogen states such as hypothalamic amenorrhea, and the absence of response in polycystic ovarian syndrome, a condition that is not characterized by low levels of estrogen, imply that factors in addition to gonadal steroids influence endogenous opioid tone.

Thus there is a complex, interdependent, multifaceted interaction of steroids, opioids, catecholamines, and other neurotransmitters in the regulation of GnRH and gonadotropin pulsatile discharge in women.

Hypothalamic amenorrhea: Clinical perspectives, pathophysiology, and management

James H. Liu, MD
Cincinnati, Ohio

The development of functional hypothalamic amenorrhea reflects an individual's response to environmental stressors and life-style variables. In this disorder there are no detectable anatomic abnormalities with respect to the hypothalamic-pituitary-ovarian-endometrial axis. Current evidence suggests that the common underlying defect is a decrease in the activity of the hypothalamic gonadotropin-releasing hormone pulse generator. Of the neuroendocrine factors that appear to regulate gonadotropin-releasing hormone activity, the opiate and dopamine neuronal systems have been implicated as factors that are responsible in part for the decreased secretion of gonadotropin-releasing hormone. Because of the functional nature of this disorder, reactivation of the hypothalamic-pituitary unit would be expected to take place in most women after accommodation to environmental stressors or modification in life-style. For women with persistent anovulation, treatment with estrogen-replacement therapy should be offered. In those desiring fertility, ovulation induction with pulsatile gonadotropin-releasing hormone would be the most effective modality. (AM J OBSTET GYNECOL 1990;163:1732-6.)

Key words: Hypothalamic amenorrhea, gonadotropin-releasing hormone, environmental stressors, opiate, dopamine

Amenorrhea associated with hypoestrogenism, normal or low levels of follicle-stimulating hormone (FSH), and psychogenic factors was originally described by Klinefelter et al.[1] in 1973. They were the first to coin the term "hypothalamic hypoestrinism" and postulated that this disorder was caused by the "failure of the hypothalamic-pituitary nervous pathways to release luteinizing hormone from the anterior pituitary." In recent years many studies have shown that individuals with hypothalamic amenorrhea have intact pituitary-ovarian-endometrial function[2-4] and the common underlying defect in this disorder is a deficiency in pulsatile secretion of gonadotropin-releasing hormone (GnRH).[5-7] Unfortunately, the neuroendocrine basis that can account for the decrease in GnRH-luteinizing hormone (LH) secretion remains unclear. An increasing number of studies have provided evidence that increased endogenous opiate activity plays a major role in suppressing pulsatile GnRH secretion.[6, 8] In addition, other studies have suggested that there is a functional link between environmentally and endogenously generated stress and onset of hypothalamic amenorrhea.[1, 3, 9] With our alterations in life-style and the growing emphasis on exercise, nutrition, and slenderness, the incidence of hypothalamic amenorrhea can be expected to increase.

Clinical and biochemical features of hypothalamic amenorrhea

On a clinical basis it is difficult to provide a typical profile of the individual with hypothalamic amenorrhea because functional hypothalamic amenorrhea is considered a diagnosis of exclusion. There are several other related disorders that can be considered to be caused by dysfunction of the central nervous-hypothalamic-pituitary system (Table I).

One such disorder, isolated gonadotropin deficiency, shares many of the biochemical features with functional hypothalamic amenorrhea. Isolated gonadotropin deficiency is characterized by a decrease in the secretion of endogenous GnRH leading to hypogonadotropic hypogonadism, eunuchoid features, incomplete development of secondary sexual characteristics, primary amenorrhea, and, in some cases, anosmia. Because this defect is probably the result of a failure of GnRH neurons to develop completely or migrate from the olfactory bulb to the hypothalamus during embryogenesis, hypoplasia of the olfactory bulbs can be identified in some patients.[10]

In contrast, patients with a diagnosis of functional hypothalamic amenorrhea can be defined as those who have an absence of menstrual cycles for more than 6 months in which no anatomic or organic abnormalities can be identified. Most women with this disorder have a history of normal onset of menarche with regular menstrual cycles between 26 and 35 days. These patients tend to be highly motivated, intelligent, involved in high-stress occupations, and usually thin or of normal body weight. In some patients a variety of emo-

Isolated gonadotropin deficiency
Pituitary tumors
Sheehan's syndrome
Empty-sella syndrome
Head trauma
Inappropriate prolactin secretion

tional or stressful events (e.g., divorce) preceding the onset of amenorrhea can be identified during the initial interview. Other environmental and interpersonal factors that can be uncovered include academic pressure, social maladjustment, and psychosexual difficulties. Life-style factors that should be scrutinized include a history of weight fluctuations, dietary habits, type and intensity of exercise, and use of sedatives and hypnotics.

A thorough physical examination should reveal normal secondary sexual development and fail to demonstrate abnormalities such as galactorrhea, thyroid enlargement, or signs of androgen excess. Despite findings of hypoestrogenic changes in the genital tract, these patients do not usually complain of hot flashes.

Laboratory values including LH, FSH, prolactin, and thyroid-stimulating hormone levels are in the low or normal range (Table II).[7] Estradiol levels are typically low or low normal. In general the progestin challenge test should confirm that there is a scant or absent estrogenic effect on the endometrium. To exclude an occult pituitary lesion, computerized tomographic scanning of the sella turcica should be performed.

Pulsatile GnRH-LH secretion in hypothalamic amenorrhea

Findings from several laboratories have established that there is a slowing in frequency of hypothalamic GnRH-LH secretion that is the basic underlying cause of persistent anovulation in women with hypothalamic amenorrhea.[5-7, 11] In these studies frequent peripheral blood samples were used to quantitate pulsatile LH secretion and provide an indirect assessment of GnRH secretion. These studies make the assumption that only

GnRH is capable of stimulating LH secretion and there is a close correlation between GnRH and LH secretion, as demonstrated previously in several animal models.[12, 13]

When exogenous GnRH is administered to women with hypothalamic amenorrhea, LH and FSH responses are either normal or exaggerated compared with women with eumenorrhea.[2, 14] These findings suggest that pituitary sensitivity and capacity are not impaired and the primary defect is at a central level. Examination of individual patterns of LH secretion demonstrates considerable variability in the pulsatile pattern (Fig. 1). Compared with the follicular phase of the cycle, these LH secretory patterns are characterized by alterations in LH frequency, amplitude, and, in some cases, a regression to a pubertal pattern.[5, 6] These LH patterns suggest that the activity of the GnRH pulse generator is not uniformly suppressed to the same degree in each individual. During recovery from hypothalamic amenorrhea, a reversal of the GnRH-LH secretory pattern, characterized by a sleep-associated increase in LH amplitude, is often evident.

Opioidergic and dopaminergic modulation of GnRH secretion

A growing body of evidence indicates that endogenous opiates inhibit pulsatile GnRH and LH secretion.[15, 16] In a subgroup of women with hypothalamic amenorrhea, blockade of endogenous opiate receptors by naloxone can increase LH pulse frequency and amplitude.[6, 8] In addition, long-term treatment with the opiate receptor antagonist naltrexone leads to a spontaneous return of gonadotropin secretion and ovulatory function.[17] Collectively these studies suggest that an increase in endogenous opiate activity plays a significant role in reducing pulsatile GnRH secretion in this disorder.

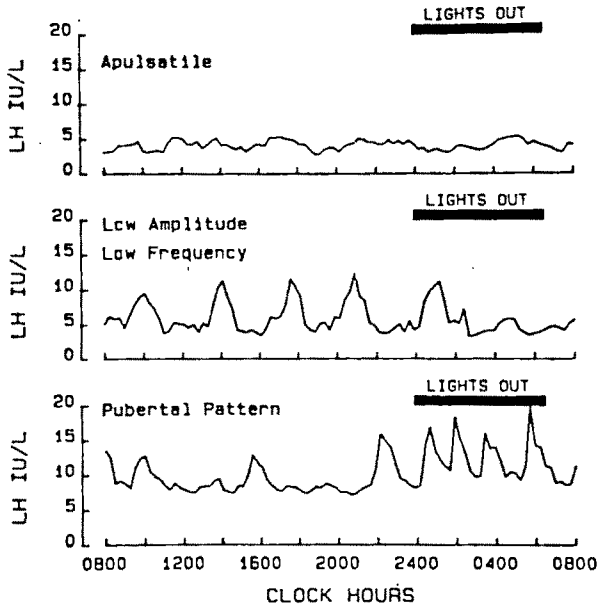

Fig. 1. Examples of the pulsatile pattern of LH in women with hypothalamic amenorrhea. Alterations in LH amplitude, frequency, and augmentation of LH secretion during the nocturnal hours are evident.

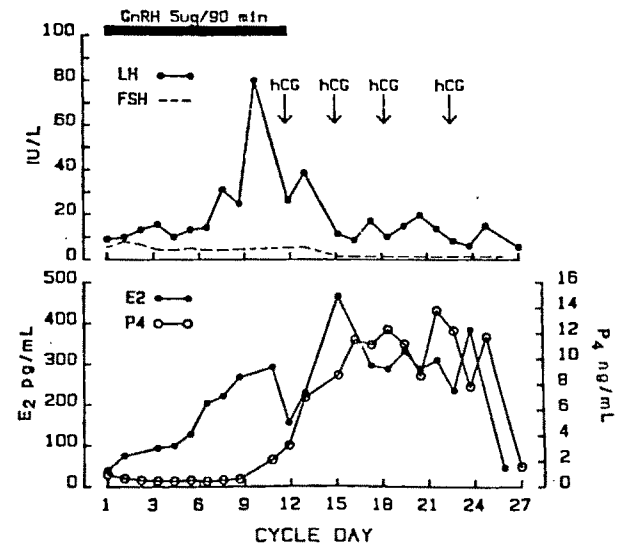

Fig. 2. LH, FSH, estradiol (E_2), and progesterone (P_4) levels during ovulation induction with intravenous pulsatile GnRH. For luteal-phase support, human chorionic gonadotropin *(hCG)*, 1500 units intramuscularly, is administered every 3 days for four doses.

Table III. Associated neuroendocrine abnormalities in hypothalamic amenorrhea

Increased amplitude and duration of nocturnal melatonin secretion[18]
Decreased 24 hr prolactin secretion with exaggerated nocturnal elevation[7]
Increased nocturnal secretion of growth hormone[7]
Blunted elevation in prolactin, adrenocorticotropic hormone, and cortisol levels with meals[9, 14]

Using a similar pharmacologic approach, Quigley et al.[8] have also demonstrated that blockade of the dopamine receptor with metaclopramide can induce an increase in LH secretion. These findings indirectly suggest that, in some patients with hypothalamic amenorrhea, there is enhanced dopaminergic activity. Because the dopaminergic and opioidergic neuronal systems are also involved in the regulation of other hypothalamic hormones, it is not surprising that there are altered secretion patterns of other hormones such as growth hormone, prolactin, adrenocorticotropic hormone, cortisol, and melatonin in women with hypothalamic amenorrhea (Table III).[7, 18]

Stress and reproductive function

The disruption of reproductive function during chronic exposure to stress has been reported in both animal species and humans.[1, 3, 19] According to Selye's original observations,[20] stress is met by increased hormonal secretions of the hypophyseal-adrenocortical axis. These effects on the reproductive axis by the hypothalamic-pituitary-adrenal axis appear to be mediated at several levels. At the hypothalamic level administration of corticotropin-releasing hormone in rats and monkeys acutely inhibits GnRH-LH release in vivo[19, 21, 22] and in vitro.[23] This inhibitory effect can be prevented by the coadministration of a corticotropin-releasing hormone receptor antagonist or reversed by naloxone, which suggests that the action of corticotropin-releasing hormone is mediated through the opioidergic system.[19, 22]

At the pituitary level the administration of adrenocorticotropic hormone can delay pubertal maturation and disrupt the reproductive cycle in adrenalectomized rats.[23] In addition, chronic hypercortisolism leads to a decrease in pituitary sensitivity to GnRH.[24]

In humans there is evidence that links stress, chronic activation of the hypothalamic-pituitary-adrenal axis, and reproductive dysfunction in athletes and women with hypothalamic amenorrhea.[9, 14] In these women there is a significant elevation in daytime cortisol levels, a delay or absent response in adrenocorticotropic hormone and cortisol secretion during the noon meal, and a blunted response to corticotropin-releasing hormone.[9, 14] These clinical studies suggest that there is a functional association between chronic stress and the onset of ovulatory dysfunction and amenorrhea.

Management of hypothalamic amenorrhea

Because of the functional nature of hypothalamic amenorrhea, a major emphasis should be placed on a

carefully conducted initial interview that focuses on life-style variables and interpersonal relationships. Significant organic disease must be excluded. In many instances spontaneous recovery of menstrual function will return after reassurance, psychologic guidance, and modification of life-style.[3] For this reason, expectant management remains a viable option. Periodic reassessment of reproductive status in these individuals (i.e., every 4 to 6 months) would be prudent.

For those women with persistent anovulation, a major concern is the long-term effect of hypoestrogenism on bone density. Unfortunately, there is very little information with regard to this aspect of hypothalamic amenorrhea from an epidemiologic perspective.[25] Based on our current understanding of bone mineral metabolism, chronic estrogen deprivation can lead to significant osteopenia that will predispose these patients to the increased risk of bone fractures. Because these patients are often reluctant to take medications, serial bone density studies may be necessary to convince them of the necessity to begin estrogen-replacement therapy.

For women who are interested in fertility, a trial of clomiphene citrate is indicated. Because clomiphene citrate displays weak estrogenic properties in a hypoestrogenic environment,[26] lower doses of clomiphene (25 mg/day for 5 days) should be used initially. In some cases higher doses of clomiphene (>100 mg/day) may exert a paradoxic effect and suppress the hypothalamic-pituitary axis.

For those women who fail to respond to clomiphene, the most logical approach would be ovulation induction with pulsatile GnRH. Because the primary underlying defect in hypothalamic amenorrhea is decreased endogenous GnRH secretion, this approach can be viewed as a form of "physiologic" replacement therapy. For women with hypothalamic amenorrhea a starting intravenous dose of GnRH of 1 to 5 μg/90 min has been shown to be effective.[27,28] Monitoring of serum estradiol levels or follicular development can be minimized because ovarian follicular response and gonadotropin output mimic the natural menstrual cycle (Fig. 2). Gonadotropin support of the corpus luteum can be maintained with either continuation of pulsatile GnRH or human chorionic gonadotropin, 1500 units intramuscularly every 3 days for four doses. With the intravenous mode of GnRH therapy, ovulation rates of approximately 90%, conception rates of 25% to 30% per ovulatory cycle, and hyperstimulation rates of less than 1% have been reported in patients with hypothalamic amenorrhea.[29]

In summary, the development of functional hypothalamic amenorrhea is linked to life-style variables and environmental stressors. From a teleologic perspective, the reproductive cycle shifts into a temporary "resting phase" characterized by decreased secretion of endogenous GnRH under these unfavorable conditions. Neuroendocrine factors, which appear to modulate reduced GnRH activity in this disorder, include the opiate and dopamine neuronal systems. In most women spontaneous reactivation of the hypothalamic-pituitary unit will take place after accommodation to stress factors or modification in life-style.

Discussion

Audience. How do you normally maintain the luteal phase?

Dr. Liu. You tend to have fewer problems with the intravenous sites if you limit the infusion duration of intravenous GnRH to 14 to 16 days. Also, if you plan to use intravenous GnRH in consecutive cycles, you do not want to exhaust potential intravenous sites. For these reasons, we tend to use hCG to maintain the luteal phase.

Audience. How did you determine the correct dose and schedule for hCG in the luteal phase?

Dr. Liu. First, we calculated, on the basis of half-life of exogenous hCG, how long we needed to give hCG and at what intervals. Every 3 days was an approximation. We determined that 1500 units was the minimum dose that could maintain progesterone production in a simulated luteal phase.

Polycystic ovary syndrome: Abnormalities and management with pulsatile gonadotropin-releasing hormone and gonadotropin-releasing hormone analogs

Marco Filicori, MD, Carlo Flamigni, MD, Elisabetta Campaniello, MD, Maria Cristina Meriggiola, MD, Laura Michelacci, MD,[a] Alessandro Valdiserri, MD, and Paola Ferrari, BSc

Bologna, Italy

Ovulation induction with pulsatile gonadotropin-releasing hormone achieves high ovulatory and pregnancy rates in hypogonadotropic hypogonadism while limiting the occurrence of ovarian hyperstimulation and multiple pregnancy. However, this form of therapy is apparently less effective in polycystic ovary syndrome. The administration of a gonadotropin-releasing hormone analog for 4 to 8 weeks before the initiation of pulsatile gonadotropin-releasing hormone ovulation induction can temporarily correct endocrine abnormalities of polycystic ovary syndrome, such as excessive luteinizing hormone and androgen secretion, and improve ovulatory and pregnancy rates in these patients. For optimal results, this pretreatment should probably be repeated before each pulsatile gonadotropin-releasing hormone ovulation induction cycle. Obesity is associated with a lower success rate, and spontaneous abortion remains a prominent complication in polycystic ovary syndrome even after gonadotropin-releasing hormone analog suppression. With this regimen the risks of ovarian hyperstimulation and multiple pregnancy are virtually abolished. Thus, pulsatile gonadotropin-releasing hormone appears to be highly effective and safe for ovulation induction in patients with polycystic ovary syndrome also, provided that this treatment is preceded by pituitary-ovarian suppression with a gonadotropin-releasing hormone analog. (AM J OBSTET GYNECOL 1990;163:1737-42.)

Key words: Pulsatile gonadotropin-releasing hormone, polycystic ovary syndrome, GnRH analog, ovulation induction

Polycystic ovary syndrome is a disorder frequently encountered among patients seen in gynecologic and reproductive endocrine clinics. Common complaints of polycystic ovary syndrome include hirsutism, obesity, menstrual disorders (mainly oligomenorrhea), and infertility. Anovulation is common and ovulation induction is often resorted to for treatment of infertility in this disorder.

Several hormones are secreted abnormally in polycystic ovary syndrome (Fig. 1). Excessive androgen levels are common and cause acne and hirsutism; elevated intraovarian androgens also affect folliculogenesis and may participate in the pathogenesis of anovulation.[1] Although large amounts of excessive androgens and androgen substrate appear to be produced by the ovary, the adrenal gland may contribute substantially to hyperandrogenism in polycystic ovary syndrome.[2] A high pituitary output of luteinizing hormone (LH) is a frequent finding in polycystic ovary syndrome. The episodic secretion of LH is deranged; LH peaks are of greater amplitude than in normal women in the follicular phase of the menstrual cycle.[3-6] Excessive frequency of gonadotropin-releasing hormone (GnRH)–induced LH pulses may also be present,[3, 4, 7] although this feature is still the subject of some controversy.[5, 6] Pituitary sensitivity is also increased so that large amounts of gonadotropins are secreted when the pituitary gland is challenged with exogenous GnRH[8]; this derangement is probably responsible for the elevation of LH pulse amplitude present in polycystic ovary syndrome.

Excessive androgen levels indirectly affect gonadotropin secretion through various mechanisms. Androstenedione is peripherally converted to estrone; androgens also lower sex hormone–binding globulin levels so that increased amounts of unbound androgens and unbound 17β-estradiol are present in polycystic ovary syndrome.[9] These high estrone and free 17β-estradiol levels may act at the pituitary level to increase LH and follicle-stimulating hormone (FSH) reserve. This vicious cycle of high LH output, excessive androgen secretion, and elevated weak estrogen levels participates critically in the maintenance of deranged hor-

monal dynamics and the pathogenesis of anovulation in polycystic ovary syndrome.

Obesity may further complicate the endocrine picture in polycystic ovary syndrome. Obese patients with polycystic ovary syndrome secrete excessive amounts of insulin that may interact with insulin-like growth factor receptors in the ovary.[10] The synergistic action of LH and insulin may worsen ovarian androgen secretion and affect folliculogenesis. Weight loss is associated with a resumption of more regular menstrual function in women with polycystic ovary syndrome.[11]

Treatment of polycystic ovary syndrome

The specific cause of polycystic ovary syndrome is still obscure; furthermore, rather than being a single entity, polycystic ovary syndrome can be the end point of several endocrine disorders. Thus, physicians are often forced to treat symptoms instead of being able to solve the basic pathogenetic mechanism involved in this disorder. Drugs commonly used in the treatment of hirsutism include estrogen/progestogen combinations,[12] cyproterone acetate,[13] and spironolactone.[14] With the exception of spironolactone, these medications block ovarian function and prevent ovulation. GnRH analogs have also been used in the treatment of polycystic ovary syndrome because they suppress pituitary LH secretion and create a transitory and rapidly reversible condition of hypogonadotropic hypogonadism[15]; ovarian androgens are reduced and hirsutism improves during this treatment. Unfortunately, the profound hypoestrogenic state associated with GnRH analog administration prevents long-term (>6 months) treatment of polycystic ovary syndrome with this class of medications. At the suspension of GnRH analog administration, spontaneous menstrual cyclicity usually does not resume in patients with polycystic ovary syndrome who were anovulatory before GnRH analog treatment.[16]

Ovulation induction is often resorted to in women with polycystic ovary syndrome willing to conceive. Administration of clomiphene citrate results in an apparently high rate of ovulation but may be associated with luteal phase defects.[17] A discrepancy exists between the incidence of apparent ovulation and conception achieved with clomiphene; thus more effective means of ovulation induction are often needed. Human menopausal gonadotropins (hMG) and purified FSH may be used in patients with polycystic ovary syndrome who are resistant to clomiphene. Purified FSH has a theoretic advantage over hMG because it should correct the imbalance between LH and FSH typical of polycystic ovary syndrome in favor of the latter hormone. However, the use of purified FSH may not be associated with significant clinical advantages over hMG.[18]

The administration of hMG can result in a greater incidence of ovarian hyperstimulations and multiple pregnancies in polycystic ovary syndrome than in other ovulatory disorders. Wang and Gemzell[19] showed that patients with polycystic ovary syndrome are particularly prone to development of these complications. Therefore, ovulation induction with hMG should be monitored with particular care in patients with polycystic ovary syndrome.

Ovulation induction with pulsatile GnRH in polycystic ovary syndrome

Because of the low incidence of complications associated with the use of pulsatile GnRH, this therapeutic modality would appear to be optimal for the treatment of patients with polycystic ovary syndrome. Unfortunately, several reports have suggested that pulsatile GnRH may be far less effective in polycystic ovary syndrome than in hypogonadotropic hypogonadism.

Ory et al.[20] gave low-dose (25 ng/kg) pulsatile GnRH to four patients with polycystic ovary syndrome for six cycles. Ovulation apparently occurred in five cycles, but an inadequate luteal function may have been present in some subjects and no pregnancies ensued. Similarly, Burger et al.[21] reported a rather high ovulatory rate (87%) in 85 treatment units, whereas only five pregnancies occurred in 3 of the 11 patients treated.

An important distinction between patients with polycystic ovary syndrome and women with multifollicular ovaries was drawn by Adams et al.[22] Patients with multifollicular ovaries had lower LH and androgen levels and normal-size ovaries; these subjects responded well to exogenous pulsatile GnRH when administered both intravenously and subcutaneously, and an ovulatory rate per cycle of 85% was achieved. Conversely, patients with large polycystic ovaries and elevated serum LH and testosterone levels obtained only a 40% ovulatory

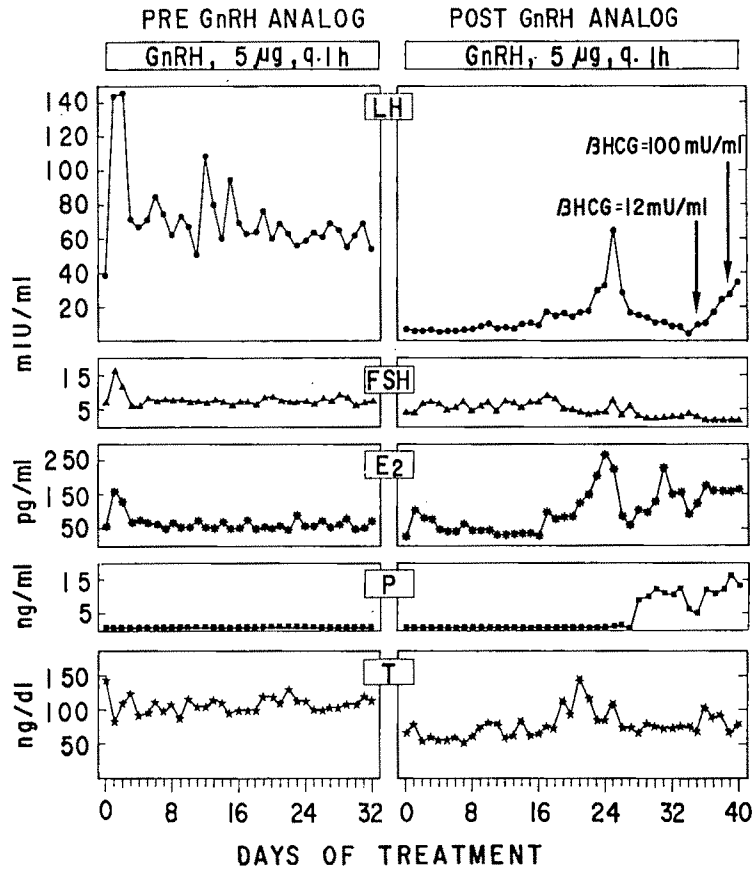

Fig. 2. Ovulation induction with pulsatile GnRH (5 μg/bolus every 60 minutes) in the same patient with polycystic ovary syndrome before *(left panels)* and after *(right panels)* GnRH analog suppression. (From Filicori M, et al. J Clin Endocrinol Metab 1988;66:327.)

rate per cycle; the success rate was similar in patients treated intravenously or subcutaneously. Thus patients with multifollicular ovaries seem to represent a different pathologic entity well differentiated from polycystic ovary syndrome and highly susceptible to pulsatile GnRH ovulation induction. These authors also found an elevated incidence of early miscarriage and abortion in polycystic ovary syndrome; only two of eight pregnancies were uneventful in these patients. The same group[23] later reported slightly better results in patients with polycystic ovary syndrome treated with a combination of subcutaneous pulsatile GnRH and clomiphene citrate; the intravenous route was resorted to in patients who failed to ovulate on the subcutaneous regimen. Nevertheless, only 87 (51%) of 170 treatment cycles were ovulatory, and conception was achieved in 23 cycles (13.5% pregnancy rate per cycle). The cumulative conception rate during a 6-month period was 60%. Lack of response was particularly evident in obese patients and subjects with higher testosterone levels. These investigators confirmed the occurrence of a high rate of spontaneous abortion in this patient population.

The administration of pulsatile GnRH for ovulation induction was found to be highly disappointing also by Hurwitz et al.[24] and Wilson et al.[25] The former group attained ovulation in only 2 of 12 treatment cycles, whereas the latter group had no success in 9 treatment periods of up to 6 weeks in 5 patients.

We recently confirmed[26] that the simple administration of intravenous pulsatile GnRH (5 μg every 60 minutes) in polycystic ovary syndrome results in low ovulatory (38% per cycle) and pregnancy rates (8% per cycle). However, a preliminary report by our group[4] suggested that pretreatment with a GnRH analog (buserelin, Hoechst-Roussel; 300 μg, subcutaneously, twice a day for 8 weeks) immediately before the initiation of pulsatile GnRH administration could improve the response of patients with polycystic ovary syndrome to this form of therapy (Fig. 2). When this approach was tested in a larger patient population of 23 patients with polycystic ovary syndrome,[26] we verified that a more physiologic endocrine pattern and higher ovulatory (90%) and pregnancy rates (38%) can be achieved with this regimen in polycystic ovary syndrome.

The pattern of hormonal secretion in patients with polycystic ovary syndrome simply stimulated with pul-

Fig. 3. (From Filicori M, et al. J Clin Endocrinol Metab 1988;66:327.)

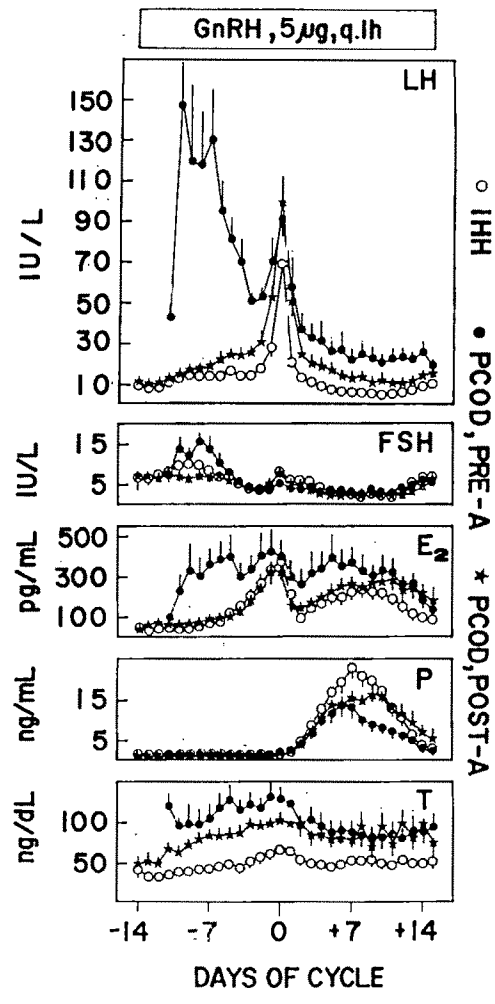

Fig. 4. Daily serum gonadotropin and gonadal steroid concentrations (mean ± SE) during pulsatile GnRH administration in ovulatory cycles of patients with primary hypogonadotropic amenorrhea *(IHH)* and polycystic ovarian disease *(PCOD)*, before *(pre-A)* and after *(post-A)* GnRH analog suppression. (From Filicori M, et al. J Clin Endocrinol Metab 1989;69:825.)

satile GnRH was characterized by high serum levels of LH, estradiol, and testosterone[26]; these features are indicative of an excessive pituitary and gonadal response in these patients. GnRH analog pretreatment in polycystic ovary syndrome induced a profound hypogonadotropic and hypogonadal state and completely abolished excessive gonadotropin and gonadal steroid secretion at the outset of pulsatile GnRH administration (Fig. 3).[4]

We then compared the endocrine response to pulsatile GnRH between patients with polycystic ovary syndrome and patients with primary amenorrhea caused by hypogonadotropic hypogonadism.[26] Pulsatile GnRH administration in this form of profound hypogonadotropic hypogonadism reproduced the pattern of reproductive hormones encountered in the normal menstrual cycle. In the cycles done after GnRH analog suppression, the profile of LH secretion closely resembled the one of patients with hypogonadotropic hypogonadism although mean LH levels were slightly more elevated (Fig. 4). Serum estradiol levels were practically superimposable in cycles done after GnRH analog suppression of patients with polycystic ovary syndrome and hypogonadotropic hypogonadism and comparable to normal levels, suggesting more physiologic folliculogenesis; progesterone levels were higher in cycles done after GnRH analog suppression than in preanalog cycles, indicating better corpus luteum function. Finally, although follicular-phase testosterone levels were lower in cycles done after GnRH analog suppression than in preanalog cycles in polycystic ovary syndrome, such differences disappeared in the luteal phase. This latter finding suggests that part of the benefits of GnRH analog suppression may be lost by 3 to 4 weeks after GnRH analog suppression. In fact, when pulsatile GnRH was continued for a second consecutive

cycle done after GnRH analog suppression, a lower ovulatory rate was obtained.

Obesity was another factor that seemed to affect the outcome of pulsatile GnRH therapy negatively in our patients. Only 15% of preanalog cycles in obese patients with polycystic ovary syndrome were ovulatory compared with 64% in nonobese subjects. GnRH analog pretreatment improved response in both groups but, although all cycles done after GnRH analog suppression were ovulatory in nonobese subjects, 25% of obese patients still did not respond to pulsatile GnRH.

Spontaneous abortion also appeared to be a conspicuous complication among our patients with polycystic ovary syndrome because it occurred in 50% of preanalog cycles and 38% of cycles done after GnRH analog suppression. However, our data suggest that miscarriage in polycystic ovary syndrome should not be related directly to high LH levels in the follicular phase,[27] because this complication also was prominent in cycles done after GnRH analog suppression that were characterized by reduced serum LH concentrations.

In conclusion, pulsatile GnRH appears to be effective in polycystic ovary syndrome only when these patients are given pretreatment and transiently rendered hypogonadotropic with a GnRH analog. By lowering pituitary LH secretion and ovarian androgen levels, this approach leads to a temporary condition of hypogonadotropic hypogonadism that creates a window of enhanced susceptibility of patients with polycystic ovary syndrome to pulsatile GnRH ovulation induction. However, to be maximally effective, GnRH analog administration should probably precede each pulsatile GnRH ovulation induction attempt because the advantages of pituitary suppression are rapidly lost. Obesity is associated with lower success rates, and spontaneous abortion remains an important complication in polycystic ovary syndrome even after GnRH analog suppression. These findings should extend the applicability of pulsatile GnRH and lead to high ovulatory and pregnancy rates and greatly reduced risks of ovarian hyperstimulation and multiple pregnancy in the great majority of patients with anovulatory disorders not associated with primary hypogonadism.

Discussion

Audience. In your studies, how did you define polycystic ovary syndrome?

Dr. Filicori. If you look in the literature, you find that the definition of this disorder is heterogeneous. We insisted that both LH and androgen levels be elevated in these patients because we were really trying to approach the problem of LH-dependent hyperandrogenism. So all the patients I have shown have both derangements.

Audience. Do you have any explanation for the increased abortion rate in patients with polycystic ovary syndrome after ovulation induction?

Dr. Filicori. We have not closely monitored these pregnancies, but I can give you our thoughts on it. We had thought that this problem could be related to an abnormal endometrium. We had hoped that by lowering both gonadotropin and gonadal steroids with the GnRH analog and thus reducing endometrial hypertrophy, we could improve on the high abortion rate we had observed in the preanalog cycles of ovulation induction. Unfortunately, the abortion rate also remained high in the postanalog cycles. This problem is probably not related to high follicular phase LH levels because, after analog suppression in these women, LH levels are very close to normal. So we really have no idea what causes this high abortion rate. In general, a high abortion rate is also present when other methods of ovulation induction are applied to patients with polycystic ovary syndrome.

Audience. Have you looked at androgen levels in the luteal phase in cycles with and without analog suppression?

Dr. Filicori. By the end of the follicular phase and throughout the luteal phase of postanalog cycles, androgen concentrations return to the preanalog levels.

Audience. You set your dose at 5 μg. Do you think that you might have a different response if you adjusted the dose on a nanogram per kilogram basis?

Dr. Filicori. We selected this dose because it is relatively close to the physiologic dose of 75 ng/kg, as reported by Drs. Santoro and Crowley. After analog suppression, the dose of GnRH is not very relevant because you usually get a slightly long follicular phase but no sign of excessive ovarian stimulation. You could try higher doses, but you may run into other problems. In hypogonadotropic hypogonadism, we have achieved good ovulatory response and pregnancy rates, with lower multiple conception rates, with the lower dose of 2.5 μg per bolus.

Audience. How often have you seen hyperstimulation in the stimulatory phase of analog treatment?

Dr. Filicori. We have never had any problem of excessive ovarian stimulation with analog administration. You may have some ovarian enlargement, but it will not require specific monitoring and usually regresses when pituitary suppression is achieved.

The luteinizing hormone–releasing hormone pulse generator in men: Abnormalities and clinical management

Alvin M. Matsumoto, MD, Kenneth M. Gross, MD, Carol B. Sheckter, MD, and William J. Bremner, MD, PhD

Seattle, Washington

Most men with hypogonadotropic eunuchoidism have absent luteinizing hormone and presumably absent luteinizing hormone–releasing hormone pulses. Pulsatile luteinizing hormone–releasing hormone therapy is effective in restoring normal gonadotropin secretion and testicular function and inducing fertility in men with hypogonadotropic eunuchoidism. Furthermore, pulsatile (versus continuous) luteinizing hormone–releasing stimulation of the pituitary gland is an absolute requirement for normal gonadotropin secretion. Men with idiopathic oligoazoospermia and selective elevation of follicle-stimulating hormone levels have slow luteinizing hormone and presumably luteinizing hormone–releasing pulse frequency. In these men, pulsatile luteinizing hormone–releasing treatment is effective in decreasing serum follicle-stimulating hormone levels, but it is unclear whether spermatogenesis and fertility are improved. (AM J OBSTET GYNECOL 1990;163:1743-52.)

Key words: Hypogonadotropic eunuchoidism, luteinizing hormone, luteinizing hormone–releasing hormone, idiopathic oligoazoospermia, follicle-stimulating hormone

Secretion of the gonadotropins, luteinizing hormone (LH), and follicle-stimulating hormone (FSH) by the anterior pituitary gland is controlled by LH-releasing hormone (LHRH) secretion from the hypothalamus. LHRH is released episodically into the hypophyseal portal system and stimulates the pulsatile secretion of LH and FSH into the peripheral circulation, which in turn regulate gonadal function.

Because of its short circulating half-life,[1] LHRH is found in highest concentrations in the hypophyseal portal circulation and is difficult to detect in peripheral blood, making direct clinical assessment of pulsatile LHRH secretion impossible. Studies in experimental animals have confirmed that the pattern of pulsatile LH secretion into peripheral blood is a very good index of episodic LHRH release from the hypothalamus.[2, 3] Therefore we and others have used frequent blood-sampling studies to characterize LH pulse patterns carefully as indexes of hypothalamic LHRH pulse-generator activity in humans.[4, 5]

Two major disorders of LHRH pulse generation have been identified by comparing the patterns of pulsatile LH secretion in these disorders with those of normal men: (1) hypogonadotropic eunuchoidism or idiopathic hypogonadotropic hypogonadism and (2) idiopathic oligoazoospermia with selectively elevated serum FSH levels.

LHRH pulse generator in hypogonadotropic eunuchoidism

Hypogonadotropic eunuchoidism is a heterogeneous disorder characterized by failure to undergo normal pubertal development (usually by 18 years of age), low serum testosterone levels, low or normal serum gonadotropin concentrations, and otherwise normal anterior pituitary functioning.[6-8]

The clinical presentation of hypogonadotropic eunuchoidism is variable because of differences in the onset and severity of the disorder. The hypogonadotropic hypogonadism is often associated with anosmia or hyposomia (Kallmann's syndrome) and other midline morphologic and functional defects such as cleft lip and palate.[6, 8] The mode of inheritance of hypogonadotropic eunuchoidism is variable.[6, 7] The underlying pathophysiology of the hypogonadotropic hypogonadism is presumed to be relative deficiency of LHRH secretion.

To characterize the abnormalities in the LHRH pulse generator in men with hypogonadotropic eunuchoidism, frequent blood-sampling studies (e.g., every 10 minutes for 24 hours) have been performed to define the secretory patterns of hypogonadotropic eunuchoidism, which reflect those of LHRH.[5, 9] Compared with

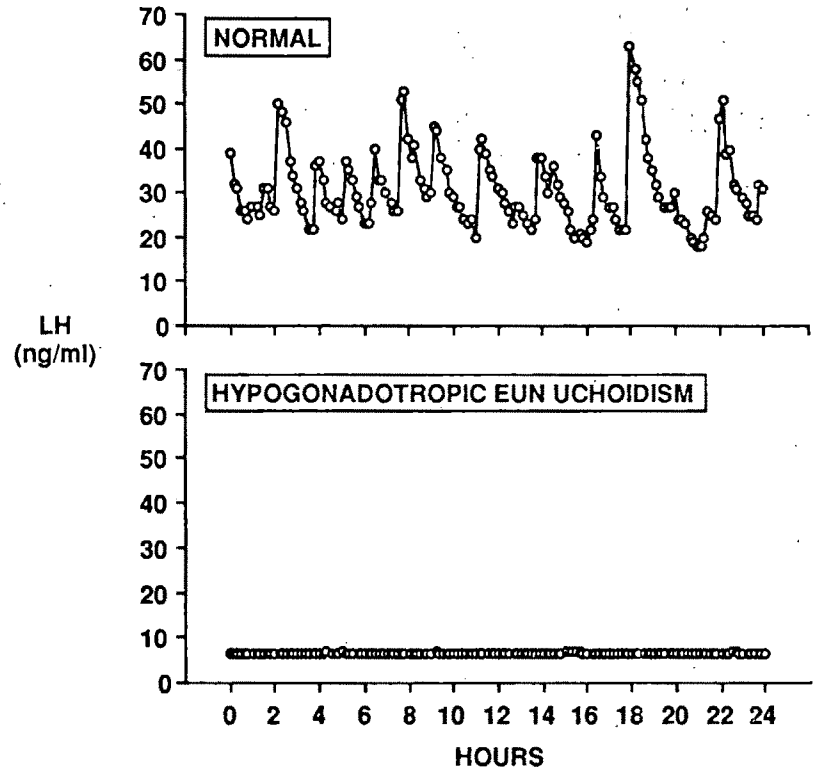

Fig. 1. LH pulse patterns in a normal man *(top)* and a man with hypogonadotropic eunuchoidism *(bottom)*, as determined on frequent blood sampling studies performed every 10 minutes for 24 hours. Note the absence of spontaneous LH pulses in the man with hypogonadotropic eunuchoidism.

normal men who demonstrate LH pulses every 100 to 120 minutes, the vast majority (more than 90%) of men with hypogonadotropic eunuchoidism have no detectable LH pulses during frequent blood sampling (i.e., an apulsatile pattern[5, 9]) (Fig. 1), suggesting absent or severely reduced LHRH pulse generation. In other men with hypogonadotropic eunuchoidism, decreases in LH pulse amplitude or frequency have been reported,[5, 9] suggesting disordered LHRH pulse generation.

LHRH pulse generator in oligoazoospermia with selective elevation of FSH levels

Approximately 5% to 6% of men in the reproductive age group are infertile. The majority of infertile men have disordered spermatogenesis of unknown cause (i.e., idiopathic oligoazoospermia). Approximately 20% of men with oligoazoospermia have elevated serum FSH and normal serum LH and testosterone levels.[10]

Several mechanisms have been proposed to explain the selective elevations in FSH relative to LH levels in these men, including increased pituitary stimulation by a separate FSH-releasing factor and decreased testicular production of negative feedback factors, such as inhibin[11] and/or sex steroids.[12] We and others have found evidence for an alternative hypothesis to explain selective elevation of FSH levels (i.e., that the frequency of LHRH stimulation of the pituitary gland is capable of differentially regulating FSH and LH levels).[13, 14]

Men with selectively increased FSH levels often demonstrate a reduced LH pulse frequency compared with normal men (Fig. 2). We performed frequent blood sampling every 10 minutes for 24 hours to characterize LH pulse patterns in a group of five men with elevated FSH and normal LH and testosterone levels and seven age-matched normal men. Men with selective elevations in FSH levels had fewer LH pulses per 24 hours (10.6 ± 0.5, mean ± SEM) than had normal men (12.9 ± 0.6; $p < 0.01$), with no significant differences in LH pulse amplitude and total and free testosterone and estradiol levels.[13] Other investigators have also found a reduced LH pulse frequency in men with selective elevations in FSH levels compared with normal men.[14] These findings suggest that the frequency of LHRH pulse generation is reduced in men with idiopathic oligoazoospermia and selective elevation in FSH levels.

The spermatogenic defect in men with idiopathic oligoazoospermia has been attributed to a primary testicular disorder. However, there is generally no history of known causes of testicular damage, and biopsy speci-

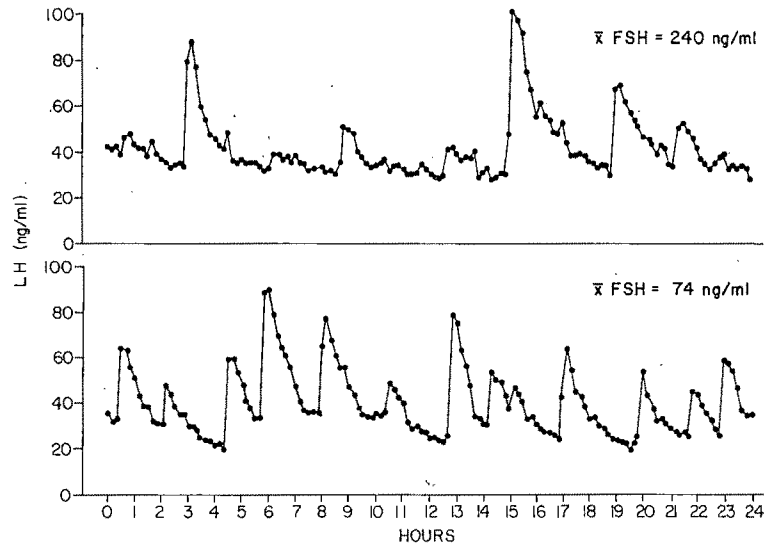

Fig. 2. LH pulse patterns in a man with idiopathic oligoazoospermia and selective elevation of serum FSH levels *(top)* and a normal man *(bottom)*, as determined on frequent blood-sampling studies performed every 10 minutes for 24 hours. Note the decreased frequency of spontaneous LH pulses in the man with oligoazoospermia and selective elevations of FSH levels.

mens of testes do not demonstrate pathologic correlates of injury, such as inflammation or fibrosis.[10] Therefore it is possible that some men with idiopathic oligoazoospermia may have a primary hypothalamic rather than testicular disorder, resulting in decreased LHRH pulse frequency, selective elevations in FSH levels, and disordered spermatogenesis as a result of the altered hormonal milieu. We and others are beginning to test this hypothesis by determining the effect of long-term pulsatile LHRH administration at increased pulse frequencies on sperm production in men with idiopathic oligoazoospermia and selective elevations in FSH levels (see below).

Treatment of hypogonadotropic eunuchoidism

Most men with hypogonadotropic eunuchoidism have deficient hypothalamic LHRH pulse generation, resulting in absent pulsatile gonadotropin secretion and lack of spontaneous pubertal development. Depending on the clinical situation, hypogonadotropic eunuchoidism may be treated with testosterone, gonadotropins, or "physiologic" pulsatile LHRH replacement.

If pubertal development and normal sexual functioning are desired but induction of fertility is not an issue, treatment of hypogonadotropic eunuchoidism is most practically accomplished with testosterone therapy. A long-acting 17β-hydroxyl ester of testosterone, such as testosterone enanthate or cypionate, 100 to 200 mg intramuscularly every 10 days to 2 weeks, results in significant virilization by 4 to 6 months of treatment.[15] The development of longer-acting analogs of testosterone may reduce the requirement for injections to every 3 to 4 months.

When stimulation of sperm production and induction of fertility are desired, gonadotropin or pulsatile LHRH therapy is required. Gonadotropin therapy is usually initiated with a preparation containing LH-like activity alone, such as human chorionic gonadotropin (hCG), 1000 to 3000 units subcutaneously or intramuscularly two to three times weekly for 6 months, to stimulate testicular steroidogenesis and induce virilization.[16-19] In some men, treatment with hCG alone may also induce spermatogenesis. However, in most men with hypogonadotropic eunuchoidism a preparation with FSH activity, such as human menopausal gonadotropin, 37.5 to 150 units subcutaneously or intramuscularly two to three times weekly, must be coadministered with hCG for another 6 months to 1 year to stimulate sperm production and induce fertility.[16-19] Prior testosterone therapy does not alter subsequent testicular responsiveness to gonadotropin therapy.[18, 20]

With the availability of LHRH for clinical use and portable, automatic infusion pumps, long-term, physiologic LHRH-replacement therapy for hypogonadotropic eunuchoidism has become a practical therapeutic option for men with hypogonadotropic eunuchoidism. In general, low doses (5 to 20 μg) of subcutaneous LHRH are administered at a frequency similar to that in normal men (i.e., every 2 hours).[5, 21] Pulsatile LHRH administration in men with hypogonadotropic eunuchoidism results in a rapid restoration of pituitary gonadotropin secretion by several weeks of treatment (Fig. 3) and normalization of testosterone secretion during the initial 3 months of therapy.[22] Continued pulsatile LHRH treatment for several months or years can stimulate sperm production and induce fer-

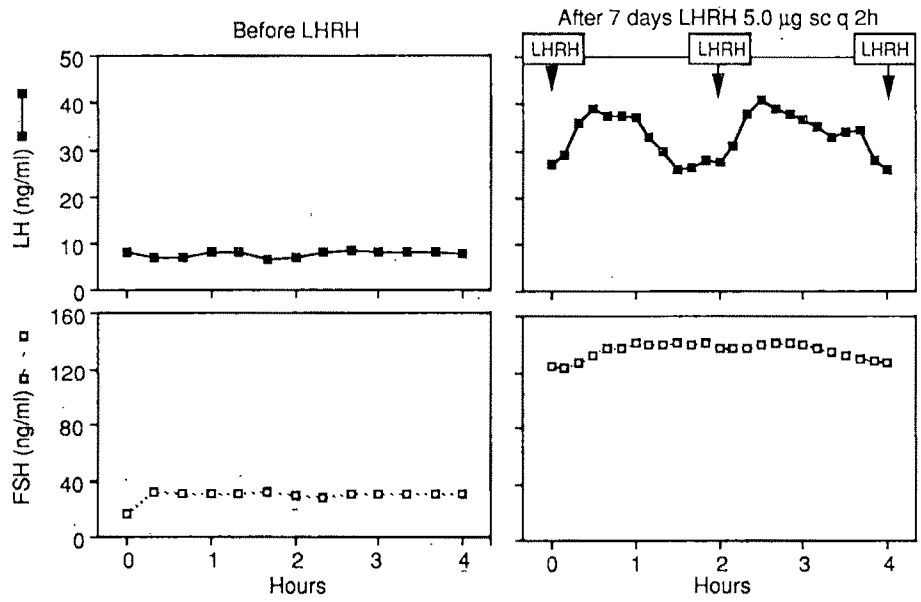

Fig. 3. Mean serum LH *(top)* and FSH *(bottom)* levels during frequent blood sampling every 20 minutes for 4 hours in four men with hypogonadotropic eunuchoidism before *(left)* and after 7 days of pulsatile LHRH therapy (5 μg subcutaneously every 2 hours). LH and FSH levels are low and there are no spontaneous LH pulsations before LHRH therapy. After 7 days of pulsatile LHRH treatment, both LH and FSH levels increase into the normal adult male range (8 to 60 ng/ml and 30 to 230 mg/ml, respectively), and discrete LH pulses follow each LHRH bolus, mimicking a normal physiologic LH pulse pattern.

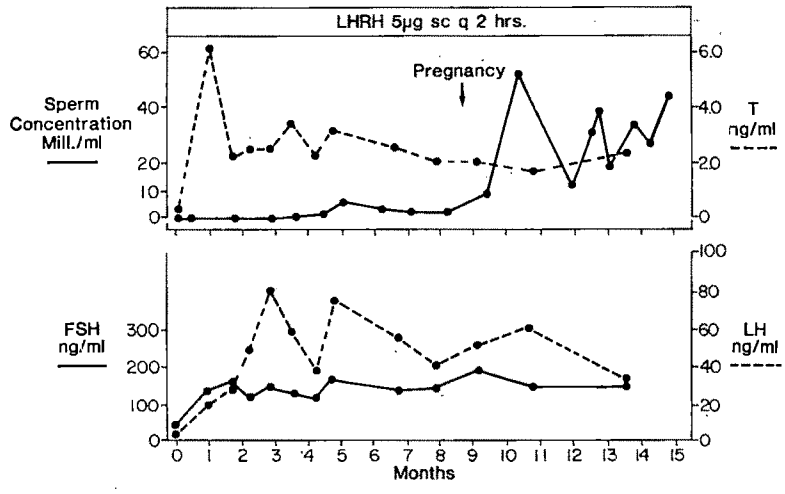

Fig. 4. Testicular *(top)* and gonadotropin *(bottom)* responses to long-term pulsatile LHRH therapy (5 μg every 2 hours for 15 months) in a man with hypogonadotropic eunuchoidism. Pulsatile LHRH treatment increases LH, FSH, and testosterone *(T)* levels into the normal adult male range by 1 month and stimulates sperm production by 9 months, resulting in fertility. (From Matsumoto AM, Bremner WJ. Bailliere's Clin Endocrinol Metab 1987;1:71.)

tility in men with hypogonadotropic eunuchoidism (Fig. 4).[21,22] The ability of exogenous pulsatile LHRH administration to restore pituitary gonadotropin and testicular function is consistent with the hypothesis that hypogonadotropic eunuchoidism is caused by a deficiency in LHRH pulse generation.

Previous studies in hypothalamic-lesioned, LHRH-deficient monkeys have demonstrated that a pulsatile mode of LHRH administration is absolutely necessary for normal pituitary gonadotropin secretion, whereas continuous administration failed to maintain normal gonadotropin levels.[23] In humans continuous

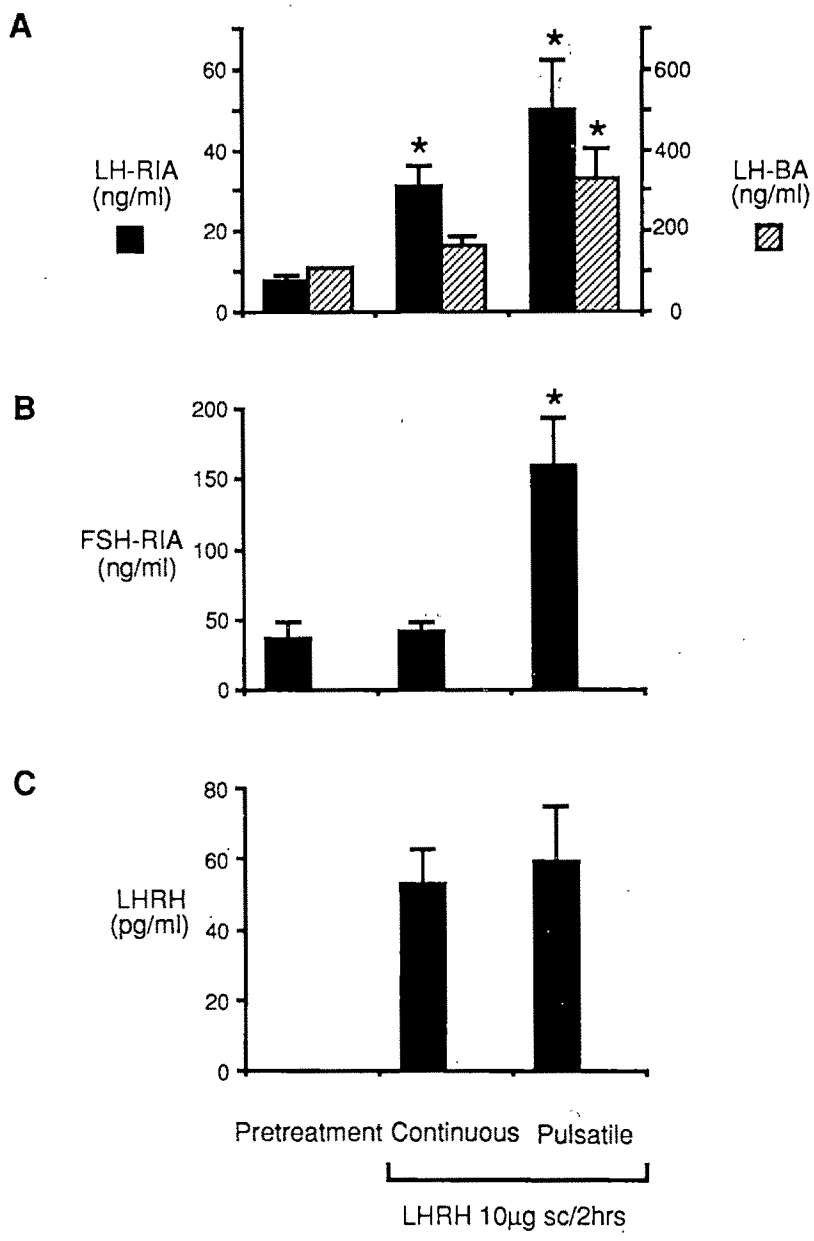

Fig. 5. Mean (±SEM) serum LH by radioimmunoassay *(RIA)* and bioassay *(BA)*, FSH, RIA, and LHRH levels in four men with hypogonadotropic eunuchoidism before (pretreatment) and at the end of 1 week each of continuous and pulsatile LHRH infusions (10 μg every 2 hours). Compared with pretreatment values, serum LH-RIA levels *(solid bars, A)* increased significantly during both continuous and pulsatile LHRH treatment. However, compared with pretreatment levels, LH-BA *(hatched bars, A)* and FSH-RIA *(B)* were not significantly different during the continuous regimen but did increase significantly during pulsatile LHRH administration. LHRH concentrations *(C)* were similar during the continuous and pulsatile regimens. $*p < 0.05$, compared with pretreatment values. (From Matsumoto AM, Gross KM, Bremner WJ. The physiological significance of pulsatile LHRH secretion in man: gonadotropin responses to physiological doses of pulsatile versus continuous LHRH administration. Int J Androl [in press]. Copyright 1990 by Scriptor Publisher ApS, Copenhagen.)

administration of markedly supraphysiologic LHRH doses[24, 25] or treatment with very potent, long-acting LHRH agonistic analogs[26] initially stimulates and then suppresses LH and FSH secretion. However, it was not known whether continuous administration of lower, more physiologic doses of LHRH (i.e., dosages known to be effective in restoring testicular function when given in a pulsatile manner) could stimulate normal pituitary gonadotropin secretion in humans.

To assess the physiologic significance of pulsatile LHRH stimulation of the pituitary gland, we compared the gonadotropin responses to a physiologic dose of

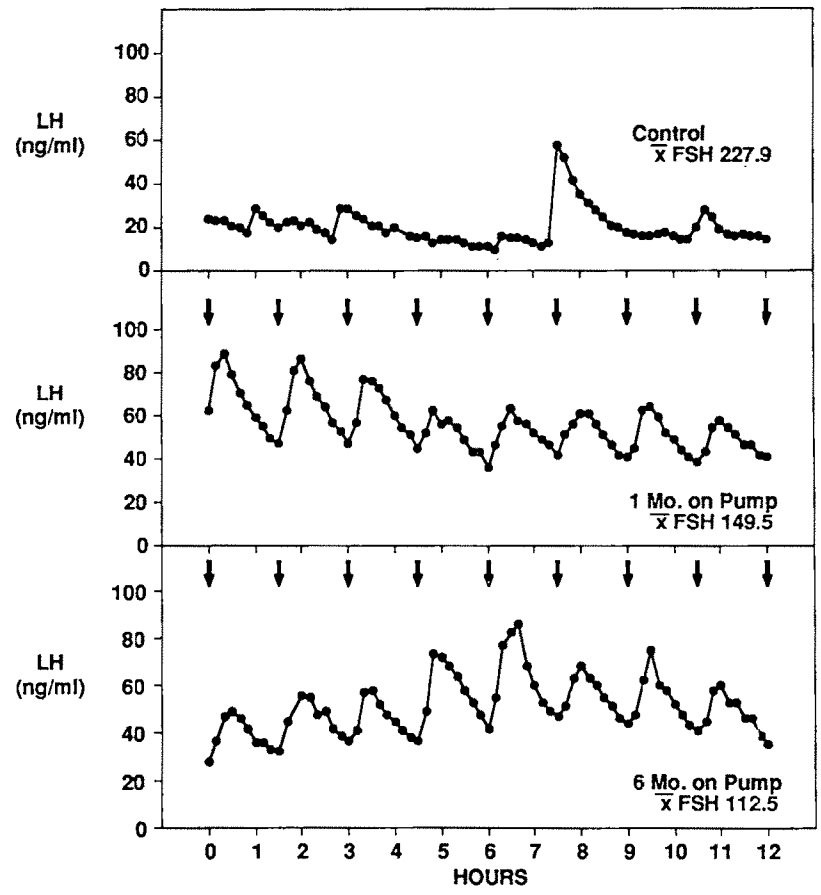

Fig. 6. Serum LH levels during frequent blood sampling every 10 minutes for 12 hours in a man with idiopathic oligoazoospermia and selective elevation of FSH levels before (control) and 1 and 6 months after pulsatile LHRH therapy (5 μg every 90 minutes). *Arrows* indicate the timing of LHRH pulses delivered by an automatic, portable infusion pump. Note that long-term pulsatile LHRH treatment increased the LH pulse frequency and mean LH levels while decreasing mean FSH levels.

LHRH administered in pulsatile versus continuous pattern in four men with hypogonadotropic eunuchoidism.[27] These men stopped hormone treatment for 5 to 6 weeks before being studied (pretreatment) and then were treated with LHRH, 5 μg subcutaneously every 2 hours for 1 week, to prime pituitary responsiveness. After this period of LHRH priming, each man received the same physiologic dose (10 μg) subcutaneously every 2 hours in a pulsatile fashion for 1 week and as a continuous infusion for 1 week, in varying order. Frequent blood sampling for LH, FSH, and LHRH was performed every 20 minutes for 4 hours during the pretreatment period and at the end of each LHRH regimen. We found that pulsatile LHRH administration in a physiologic dose stimulated normal pituitary LH and FSH secretion (Fig. 5). In contrast, continuous LHRH infusion of the same physiologic LHRH dose increased immunoreactive LH levels but did not stimulate bioactive LH levels or FSH levels above pretreatment values (Fig. 5). Serum LHRH (Fig. 5), testosterone, and estradiol levels were comparable during the pulsatile and continuous infusions. These results demonstrate that a pulsatile versus continuous LHRH signal is an absolute requirement for normal pituitary gonadotropin secretion in men. Therefore, they suggest that low-dose continuous LHRH administration is unlikely to stimulate normal testicular function.

Treatment of men with oligoazoospermia who demonstrate selective elevations of FSH levels

Infertile men with idiopathic oligoazoospermia and high serum FSH levels are considered to have irreversible seminiferous tubular damage. Many therapeutic modalities have been tried but have been uniformly unsuccessful in improving sperm production and fertility in these men. However, compared with normal men, men with idiopathic oligoazoospermia and selective elevation of FSH levels demonstrate a decreased frequency of spontaneous LH pulses. This raises the possibility that some of these men may have a primary abnormality of hypothalamic LHRH pulse generation. We hypothesized that the disordered spermatogenesis

in these men may be a consequence of the altered hormonal milieu induced by the abnormally slow LHRH pulse frequency, and LHRH administration at more rapid pulse frequencies may reduce FSH levels and improve sperm production.

As an initial test of this hypothesis, we have shown that short-term administration of LHRH at increasing pulse frequencies results in a progressive decrease in serum FSH levels into the normal range, without significant changes in serum LH, testosterone, and estradiol levels.[28] Similar findings have been reported by others.[29]

The effects of LHRH on LH and FSH levels in our study are consistent with previous work in animals[30-32] and men,[13, 28, 29, 33] which has shown that increasing the LHRH pulse frequency leads to more rapid LH pulses but lower mean FSH levels. Conversely, slowing the LHRH pulse frequency led to slower LH pulses and higher FSH levels. This finding of a differential effect of LHRH pulse frequency on LH and FSH levels has been extended by more recent work in animals demonstrating selective control of gonadotropin subunit gene expression by the frequency of pulsatile LHRH stimulation.[34]

To test further the hypothesis that reduced LHRH pulse frequency may cause or contribute to the spermatogenetic defect in men with idiopathic oligoazoospermia and selective elevation of FSH levels, we tested the effects of more prolonged (6 to 12 months) administration of pulsatile LHRH at a relatively rapid pulse frequency.

In this preliminary study we studied seven men with idiopathic oligoazoospermia (with mean sperm concentrations on three to six specimens during 3 months of less than 20 million/ml), elevated FSH levels (normal range 30 to 230 ng/ml), and normal LH and testosterone levels (8 to 60 ng/ml and 2.8 to 10.0 ng/ml, respectively). All subjects were infertile for more than 1 year but were otherwise healthy as determined by history and physical examination. None had known primary testicular disease and testis size ranged from 15 to 25 ml.

After a 3-month control period during which no hormones were administered, subjects began a 6-month treatment period throughout which they received LHRH, 5 μg subcutaneously every 90 minutes, into the abdominal wall by a portable automatic infusion pump (Zyklomat; Ferring Laboratories, Suffern, N.Y.). In two men pulsatile LHRH treatment at the same dosage was continued for 12 months. At the end of the treatment period, LHRH was discontinued and subjects were followed up for an additional 3 months (recovery period).

Throughout the entire study, seminal fluid analyses[35, 36] were performed every 2 weeks on semen samples obtained by masturbation after 48 hours of abstinence from ejaculation. Frequent blood sampling for LH and FSH levels by radioimmunoassay[4, 36] was performed every 10 minutes for 12 hours at the end of the control period, after 1 and 6 months of treatment, and at the end of the recovery period; testosterone and estradiol levels were measured by radioimmunoassay[37] in single samples at the beginning of the frequent sampling studies (7:00 to 9:00 AM).

During the control period, all subjects demonstrated a slow spontaneous LH pulse frequency typical of this group of patients.[13] After 1 and 6 months of LHRH treatment, 5 μg every 90 minutes, LH pulse frequency increased and the LH patterns in all men were directly related to the activity of the LHRH pump (Fig. 6). After exogenous LHRH was discontinued, LH pulse frequency reverted to the typically slower frequency exhibited in the control period.

Compared with control levels (41 ± 4 ng/ml), LH levels increased significantly after 1 and 6 months of LHRH treatment (70 ± 7 and 70 ± 13 ng/ml, respectively; both $p < 0.05$). Three months after discontinuation of LHRH, LH levels decreased to 35 ± 5 ng/ml and were comparable to control values. During the control period, FSH levels (311 ± 25 ng/ml) were considerably higher than the upper limit of the normal range for men. FSH levels decreased after 1 and 6 months of LHRH treatment to 236 ± 30 and 264 ± 52 ng/ml, respectively (borderline significance, $p < 0.09$), and rose to near control values (300 ± 42 ng/ml) in the recovery period.

Testosterone levels increased from 3.9 ± 0.2 ng/ml during the control period to 4.6 ± 0.7 and 5.4 ± 0.7 ng/ml after 1 and 6 months of LHRH treatment, respectively. Three months after LHRH therapy was completed, testosterone levels decreased to 3.3 ± 0.3 ng/ml. During the control period, estradiol levels were 26 ± 4 pg/ml, rose to 47 ± 5 pg/ml and 52 ± 9 pg/ml after 1 and 6 months of LHRH treatment, respectively, and then decreased to 35 ± 9 pg/ml at the end of the recovery period.

Before the LHRH treatment, five of seven men had azoospermia. No sperm appeared in the ejaculates of the subjects with azoospermia at any time during the study period. One man with control sperm counts of 0.6 to 7.0 million/ml remained severely oligospermic and infertile during LHRH therapy. The final subject had less severe oligospermia at baseline (sperm counts 2.0 to 26.2 million/ml). Although sustained improvement in his sperm counts during pulsatile LHRH treatment (2.8 to 37.4 million/ml) could not be established, this man impregnated his wife after 3 months of LHRH therapy. In two men, continuing LHRH therapy for as long as 12 months did not improve sperm production.

Our preliminary results demonstrate that the long-term administration of exogenous LHRH to men with

idiopathic oligoazoospermia with a more rapid physiologic pulse frequency can reliably increase their LH pulse frequency and decrease their mean serum FSH levels, but we were unable in these studies to demonstrate an improvement in sperm production.

Recently Bals-Pratsch et al.[38] reported results of long-term pulsatile LHRH therapy in nine men with idiopathic oligoazoospermia with elevated serum FSH levels that were similar to our findings. Six men with severe oligospermia (sperm counts <5 million/ml) and three men with azoospermia received the same LHRH dosage regimen that we used in our study (i.e., 5 μg subcutaneously every 90 minutes) by a portable infusion pump for 24 weeks. Despite lowering serum FSH levels, pulsatile LHRH treatment did not result in any improvement of sperm count or other seminal fluid parameters.

However, other groups have reported a stimulatory effect of long-term pulsatile LHRH treatment in men with oligospermia with elevated FSH levels. Wagner and von zur Mühlen[39] found that in some men with severe oligospermia (sperm counts <10 million/ml) and elevated serum FSH levels, pulsatile LHRH therapy (4 μg every 129 minutes) for 6 to 12 months increased progressively motile sperm density.

Recently Aulitzky et al.[40] determined the effect of long-term pulsatile LHRH treatment in men with varying degrees of oligospermia, elevated serum FSH levels, and slow spontaneous LH pulse frequency. Subjects were grouped according to the severity of their spermatogenic defect, based on the SPT score (number of type A_d *s*permatogonia *p*er *t*ubule square) and sperm density. Group 1, with the least testicular damage, had SPT scores of 1.0 or greater and sperm densities of 1 to 20 (8.84 ± 4.0) million/ml, group 2 had SPT scores of 0.25 to 1.0 and sperm densities of 1 to 20 (3.38 ± 1.75) million/ml, and group 3, with the most severe spermatogenic dysfunction, had SPT scores less than 0.25 and sperm densities of less than 1 (0.65 ± 0.31) million/ml. Administration of pulsatile LHRH (4 μg every 120 minutes) for a period of 6 months significantly increased sperm density (with three pregnancies) and serum LH levels and decreased serum FSH levels in men with less severe degrees of spermatogenic damage (i.e., groups 1 and 2). In contrast, men with severe testicular damage (group 3) failed to show significant changes in sperm density or FSH levels.

These results of Aulitsky et al. suggest that some men with idiopathic oligospermia and selective elevations in FSH levels may benefit from pulsatile LHRH treatment. Furthermore, they suggest that baseline assessment of the severity of the spermatogenic disorder (e.g., by SPT scores) may be useful in selecting patients who are more likely to respond to therapy. These findings may also help to explain why we and Bals-Pratsch et al.,[38] who studied men with severe spermatogenic dysfunction, failed to show a stimulatory effect of pulsatile LHRH therapy on sperm production.

None of the studies investigating pulsatile LHRH treatment of men with idiopathic oligoazoospermia included placebo-treated control subjects. Because sperm counts exhibit marked within-individual fluctuations in men with oligospermia, such controls are essential in determining whether pulsatile LHRH therapy indeed has a stimulatory effect on spermatogenesis. Because no other therapeutic options exist, the use of pulsatile LHRH therapy for men with idiopathic oligospermia and selective elevations of FSH levels deserves to be evaluated critically in formal double-blind, placebo-controlled clinical trials. Pulsatile LHRH treatment is the only promising new therapeutic modality on the horizon for this common and, at the present time, untreatable disorder.

In summary, using frequent measurement of blood LH levels to reflect episodic LHRH release, two major disorders of the LHRH pulse generator have been characterized in men: (1) men with hypogonadotropic eunuchoidism, most of whom lack detectable LH pulses and presumably have LHRH deficiency, and (2) men with idiopathic oligoazoospermia with selective elevations in serum FSH levels many of whom demonstrate decreased spontaneous LH pulse frequency, presumably as a result of slowed LHRH pulse generation.

In men with hypogonadotropic eunuchoidism long-term low-dose (physiologic) pulsatile LHRH administration is effective in restoring normal pituitary gonadotropin and testicular steroid and sperm production. In contrast, continuous administration of a physiologic LHRH dosage, although increasing immunoreactive LH levels, does not stimulate bioactive LH levels or FSH levels. Therefore a pulsatile LHRH stimulus pattern is an absolute requirement for normal pituitary gonadotropin secretion in men, and long-term low-dose continuous LHRH treatment is unlikely to stimulate normal testicular function.

In men with idiopathic oligoazoospermia and selective elevation of FSH levels, long-term pulsatile LHRH administration is effective in decreasing serum FSH levels. However, the efficacy of LHRH treatment in stimulating spermatogenesis and improving fertility in these men is unclear. Because this therapeutic modality holds promise as a useful treatment for a common, presently untreatable disorder, it deserves further formal clinical investigation.

Discussion

Audience. In your study of men with low sperm count, did you characterize motility, function, and morphology?

Dr. Matsumoto. The few individuals we have studied had a varying spectrum of motility. Most of them had normal motility. According to an in vitro assay of sperm function, the zona-free hamster ova sperm penetration test, the majority of these men had low-normal to reduced sperm penetration. Many have had abnormalities in morphology as well. None of the individuals had varicoceles and, from what we could derive from their histories, none had exposure to any testicular toxins.

Audience. Were you able to document any morphologic change in sperm during the course of therapy with gonadotropin-releasing hormone?

Dr. Matsumoto. We do not have a sufficient number of individuals who have been treated long term from which to draw any firm conclusions.

Gonadotropin-releasing hormone deficiency in men: Diagnosis and treatment with exogenous gonadotropin-releasing hormone

William F. Crowley, MD, and Randall W. Whitcomb, MD

Boston, Massachusetts

Idiopathic hypogonadotropic hypogonadism in men is the result of absent or abnormal secretion of gonadotropin-releasing hormone, which prevents pubertal development. Isolated gonadotropin-releasing hormone deficiency is clinically and neuroendocrinologically heterogeneous, largely because of variation in the degree of gonadotropin-releasing hormone deficiency. Treatment with pulsatile gonadotropin-releasing hormone results in normal pubertal changes and virilization. Such treatment has been uniformly successful in normalizing release of gonadotropins and secretion of testosterone. Improvement in secondary sex characteristics and induction of spermatogenesis have been achieved in most patients. Eight of nine patients desiring induction of fertility were able to father a child. Use of pulsatile gonadotropin-releasing hormone presents a powerful model in which to examine regulation of gonadotropin secretion and the role of hypothalamic gonadotropin-releasing hormone in control of the male reproductive axis. (Am J Obstet Gynecol 1990;163:1752-8.)

Key words: Gonadotropin-releasing hormone in men, idiopathic hypogonadotropic hypogonadism, apulsatile luteinizing hormone pattern, developmental arrest luteinizing hormone pattern, decreased amplitude luteinizing hormone pattern

Men with idiopathic hypogonadotropic hypogonadism fail to undergo puberty because of a deficiency in the endogenous secretion of the hypothalamic gonadotropin-releasing hormone (GnRH). Episodic discharge of GnRH appears to be the central event in the initiation of puberty. In GnRH deficiency, secondary sex characteristics fail to develop normally, and prepubertal gonadotropin and testosterone levels persist into adult life.[1]

Clinical patterns of GnRH deficiency

There are several lines of evidence that indicate the existence of a number of different forms of idiopathic hypogonadotropic hypogonadism. These include different modes of inheritance, the inconsistent association of other anomalies, and varying degrees of sexual development and responsiveness to GnRH testing in

men with idiopathic hypogonadotropic hypogonadism. The occasional development of idiopathic hypogonadotropic hypogonadism after puberty suggests that it may also occur as an acquired disorder. There appears to be greater variability therefore in clinical and neuroendocrine presentation than is generally realized.[2, 3] This is largely the result of varying degrees of GnRH deficiency.[3]

The most common clinical presentation is the complete absence of pubertal development with minimal testicular growth.[3] Serum luteinizing hormone (LH), follicle-stimulating hormone (FSH), and plasma testosterone levels are usually below the normal male range. A more severely affected subgroup of these patients has anosmia, microphallus, and incompletely descended testes with serum gonadotropin levels at or below assay detection limits.[2] This has frequently been called the Kallmann's syndrome, and genetic association with color blindness, anosmia, synkinesis, and mental defect has been described.[4] GnRH secretion may have been deficient in utero in the more severely affected group, to the extent that testosterone production was stimulated by maternal chorionic gonadotropin alone.[2]

An uncommon subset of men with isolated GnRH deficiency has a history of normal puberty and partial sexual development, but it has a subsequent decrease in libido and infertility. Hypogonadotropic hypogonadism usually develops between the ages of 20 and 35 years, with testicular volume near or within the normal adult range and biopsy evidence of normal spermatogenesis. Apparently these men have either a partial or acquired form of idiopathic hypogonadotropic hypogonadism.[2, 3]

The so-called "fertile eunuch" syndrome represents still another subset of patients in which GnRH deficiency is incomplete. There appears to be sufficient secretion of GnRH and resultant gonadotropin output to stimulate spermatogenesis and some testicular growth. There is a marked deficiency of androgen production, however, and a virtual absence of mature Leydig cells. Gonadotropin secretion is inadequate to stimulate Leydig cell production of testosterone required for full virilization.[3] Plasma FSH concentrations are in the normal adult male range, but LH levels are low.

Genetic considerations

Several studies have described kindreds with GnRH deficiency compatible with an autosomal-dominant or an autosomal-recessive mode of inheritance. In our experience with 120 consecutively studied patients, however, the majority of cases were sporadic.[3]

The defect in idiopathic hypogonadotropic hypogonadism appears to occur at a suprapituitary level and

to involve mechanisms that regulate GnRH synthesis and release. A plausible basis for such a defect would be an absent or abnormal GnRH gene.

Yang-Feng et al.[5] recently isolated the gene-encoding biosynthesis of GnRH and localized it to the short arm of chromosome 8. The structure of this gene was studied in 13 patients (11 men and 2 women) with clinically and biochemicaly documented idiopathic hypogonadotropic hypogonadism. No deletions or major rearrangements of the gene could be identified.[6]

Smaller, more subtle defects within the gene remain a possibility. Definite exclusion of point mutations will require cloning and sequencing the gene from a number of affected individuals.

Alternatively, genetic lesions outside the GnRH locus may form the basis for GnRH deficiency in idiopathic hypogonadotropic hypogonadism. Such a lesion might produce a defect in the GnRH-producing neurons or abnormalities in the neural pathways that control GnRH secretion.

Studies in animals[7] have demonstrated that GnRH-producing neurons originate embryologically in the embryonic olfactory placode outside the brain. During fetal development, they migrate to their adult locations in the hypothalamus and the olfactory tract. Defects in the pathways regulating this migration could account for the absence of GnRH secretion, as well as the anosmia observed in many patients with idiopathic hypogonadotropic hypogonadism.[7]

Differential diagnosis

Before making the diagnosis of idiopathic hypogonadotropic hypogonadism, it is important to rule out the more common hypogonadotropic states caused by a mass lesion of the hypothalamic-pituitary area. Magnetic resonance imaging or computed tomography should be an initial step in the workup of all patients with idiopathic hypogonadotropic hypogonadism. The diagnosis of isolated GnRH deficiency can only be made

in the presence of otherwise normal pituitary function and the absence of any anatomic defect.

GnRH secretion in normal men

Driven by the episodic discharge of GnRH, LH is secreted in a pulsatile fashion in men. LH then acts to stimulate production of testosterone by the Leydig cell.

Testosterone acts as the primary hormonal signal regulating secretion of LH in men. It exerts its effect predominantly through negative feedback at the level of the central nervous system and slows the frequency of pulsatile GnRH discharge. This in turn reduces pulsatile LH secretion. Testosterone may also exert a minor negative feedback effect at the anterior pituitary gland, but this is quantitatively less important.

Two features unique to neuroendocrine systems complicate the direct measurement of GnRH secretion. One is the intermittent mode of secretion of releasing factors and their evanescent character. GnRH, in particular, has a half-life of only 2 to 4 minutes. The second obstacle is the nature of the closed blood supply linking the central nervous system to the anterior pituitary gland; only a very small fraction of the GnRH secreted from the hypothalamus ever leaves this limited anatomic space. Thus GnRH levels in the peripheral circulation are very low. As a result of these difficulties, we have used monitoring of LH pulsations as an indirect assessment of GnRH secretion.

GnRH secretion was studied by LH pulsation monitoring in 15 men (aged 18 to 35 years) with a normal history of sexual development, normal testicular size, and normal seminal fluid analysis.[8] Gonadotropin levels were sampled at 10-minute intervals during a 24-hour period. A range of LH pulse frequencies varying from 7 to 17 pulses per 24 hours was observed. Pulse amplitudes and frequencies varied slightly, depending on the pulse criterion employed (Table I). Such data are used for construction of physiologically based programs of exogenous GnRH therapy.[8]

A predominant clustering of the LH pulses during sleeping hours reflects a pattern of GnRH secretion characteristic of puberty that was formerly thought to occur only at that time of life.[9] During repeated studies, however, this pattern appeared to be a reproducible finding in some of our normal subjects.[8]

Physiology of GnRH in idiopathic hypogonadotropic hypogonadism

The genetic, clinical, and biochemical heterogeneity of various subgroups of men with idiopathic hypogonadotropic hypogonadism noted above was suggestive of significant variability in the patterns of GnRH secretion and degree of GnRH deficiency. To test this hypothesis, the patterns of GnRH-induced gonadotropin secretion were characterized in 50 consecutive men with idiopathic hypogonadotropic hypogonadism and compared with those in 20 normal men.[2]

Patterns of pulsatile LH secretion were classified into three broad groups: (1) apulsatile pattern (no detectable gonadotropin pulses), (2) developmental-arrest pattern (LH pulsations occurring predominantly during the night), and (3) decreased-amplitude pattern (LH pulsations of decreased amplitude occurring day and night). Based on histories, physical examinations, and testicular biopsy findings, these groups were further divided into subsets (Table II).

Of the 50 men with idiopathic hypogonadotropic hypogonadism, 42 had an apulsatile pattern with no detectable LH or FSH pulsations. One subset of this group with apulsatile patterns (n = 32; aged 18 to 58 years) recalled no history of puberty, had a mean testicular volume of 3.3 ± 0.5 ml, and had testicular biopsy specimens revealing seminiferous tubules with a prepubertal appearance. Seventeen men in this subset had anosmia, and four had microphallus and incompletely descended testes with volumes of 1 to 2 ml. Serum gonadotropin levels were generally undetectable in these four men.

A second subset of men with apulsatile patterns (n = 10; aged 18 to 39 years) had a history of partial or complete sexual maturation with subsequent isolated idiopathic loss of sexual function. Of the three patients with histories of having normal children, one had previously fathered two children and the other two had isolated losses of potency and libido. In three of the men with histories of only partial puberty, testicular biopsy specimens demonstrated prepubertal histologic findings in the first, arrest of spermatogenesis in the second, and mature spermatogenesis in the third. All 10 of these men had an intact sense of smell, and none had microphallus or undescended testes. Mean pooled serum LH and FSH values were similar to those in the subset with no history of spontaneous puberty (Table II).

Three men (aged 18 to 24 years) had the developmental-arrest pattern of detectable LH pulsations predominantly during the night. One of these patients related the onset of puberty between the ages of 15 and 16 years. This was characterized by spontaneous daytime erections, minimal ejaculations, increased libido, and weekly shaving by age 17 years. There was no progression or decline thereafter. The other two patients recalled no pubertal symptoms. Serum LH and FSH values in these patients were within the lower range of normal and were significantly greater than those in patients with apulsatile patterns (Table II).

The decreased-amplitude pattern was seen in four men (aged 24 to 41 years). These patients had LH pulsations of abnormally low amplitude during both sleeping and waking hours. Their mean pulse amplitude was 0.8 ± 0.1 mU/ml (LER 907), which was significantly lower than the mean value in normal subjects (1.8 ± 0.2 mU/ml; $p < 0.005$). Three brothers who were in this group had an intact sense of smell, testicular volumes of 3 ml or less, and mean pooled serum testosterone levels of 34 ± 5 ng/dl. The fourth man had anosmia with testicular volumes of 12 and 15 ml and a serum testosterone level of 99 ng/dl. Serum LH and FSH levels in this group of patients were significantly below the normal range.

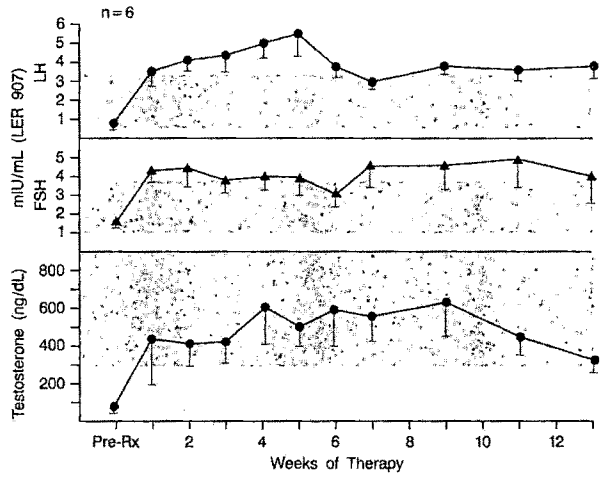

Fig. 1. Mean levels (± SE) of LH, FSH, and testosterone in six men with idiopathic hypogonadotropic hypogonadism. The dosage of GnRH during 3 months of administration was 25 ng/kg given subcutaneously every 2 hours. The *shaded areas* represent the range of normal values in men. The values for weeks 6 and 9 represent those in five of the patients, and the values for week 13 represent those in four patients. (Reprinted by permission of N Engl J Med 1982;307:1237.)

The remaining patient was difficult to classify. The amplitude and frequency of his GnRH-induced gonadotropin pulsations appeared to be normal. His serum LH value, however, was biologically inactive when tested in the dispersed rat Leydig's cell assay. Apparently the defect was the secretion of a biologically inactive LH molecule.[2,8]

We had previously reported two brothers with a relatively slow frequency of LH pulsations. They had severe gynecomastia and serum testosterone levels intermittently below the normal range.[8] The spectrum of GnRH secretory abnormalities seen in idiopathic hypogonadotropic hypogonadism therefore includes a complete absence of LH pulses, as well as disorders of amplitude and frequency, a pubertal arrest pattern, and the presence of bioinactive LH secretion.

Treatment with GnRH

Isolated GnRH deficiency has been treated by intravenous or subcutaneous pulsatile administration of GnRH. Results have been uniformly positive in terms of normalizing gonadotropin and testosterone levels. Most patients have had successful stimulation of puberty and normal virilization.

Intravenous administration produces the most physiologic GnRH pulse contour and ensuing LH response. The circumstances in which long-term intravenous maintenance is feasible, however, are obviously limited. Therefore subcutaneous administration with a programmable peristaltic infusion pump is the preferred route.

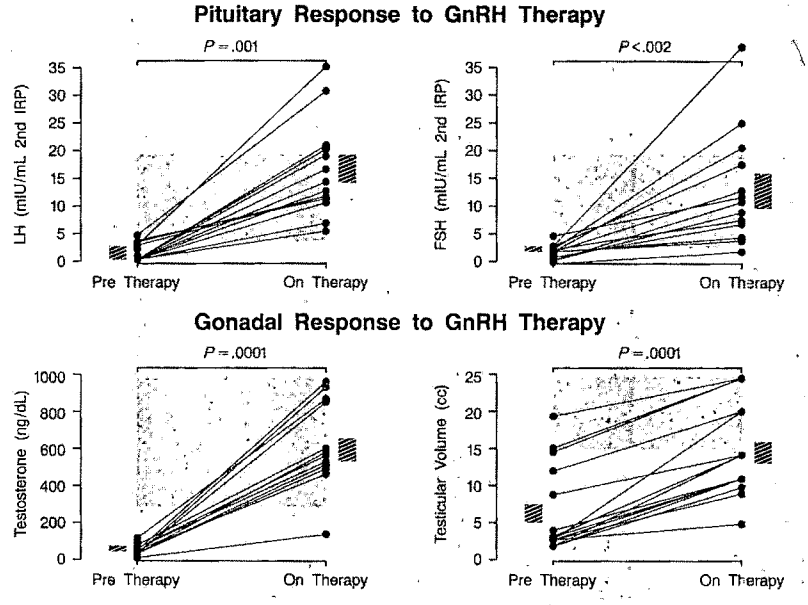

Fig. 2. Pituitary and gonadal responses of subjects with idiopathic hypogonadotropic hypogonadism before and after long-term GnRH administration. In the sole subject whose serum testosterone level did not normalize an antibody to GnRH developed before completion of his sexual maturation. The *shaded areas* indicate normal ranges for men and the *hatched bars* represent mean values for 14 patients. IRP, International Reference Preparation. (Modified from Crowley WF Jr, et al. Recent Prog Horm Res 1985;41:473.)

Administration of GnRH every 2 hours simulates the normal secretion of the endogenous hormone. This frequency of administration has been shown to be effective in GnRH-deficient men. An increase or decrease in frequency of administration results in deviations from the normal levels of both gonadotropin and testosterone. Individual GnRH dosage requirements are quite variable, ranging from 25 to 600 ng/kg in each bolus. Required dosage correlates positively with body weight and negatively with initial testicular volume.

The response of patients' serum testosterone and gonadotropin levels to GnRH administration and the rate of testicular growth should be monitored closely at 2- to 4-week intervals during long-term therapy. Eventually, regular seminal analyses should be performed. Most patients will require treatment for a minimum of 2 years to maximize testicular growth and achieve spermatogenesis.

A 100% success rate in stimulating pituitary gonadotropin output and testicular steroid secretion was observed in a series of 51 consecutive men with GnRH deficiency from the Massachusetts General Hospital.[3] In a pilot study with six patients with idiopathic hypogonadotropic hypogonadism,[1] mean serum LH values peaked during the fifth week of treatment at 4.80 ± 0.89 mU/ml and declined into the high-normal range by the seventh week. The decrease was caused by negative feedback inhibition by the sex steroids. Mean FSH levels increased to 4.77 ± 0.81 mU/ml by week 2 and remained elevated during most of the first 3 months. By the end of the first week, mean serum testosterone levels rose to the adult range and remained elevated for the first 3 months (Fig. 1).

The final pituitary and gonadal responses achieved in a group of patients with idiopathic hypogonadotropic hypogonadism receiving long-term replacement therapy with GnRH in doses ranging from 25 to 200 ng/kg are shown in Fig. 2. Only one patient failed to achieve a normal pituitary and gonadal response. An antibody to GnRH developed in this man before he could attain full sexual maturity. Changes in secondary sex characteristics induced by this regimen are shown in Table III.

Fig. 3 shows the testicular growth response in 17 patients recently treated for a minimum of 24 months with a pulsatile GnRH regimen that was adjusted to normalize both gonadotropin and testosterone secretion. Patients with larger initial gonadal size generally have the most rapid testicular growth. Individual patients with smaller initial gonadal size, however, can also achieve normal testicular volume.[3]

Spermatogenesis was induced successfully in 34 of 51 GnRH-deficient men who submitted samples for analysis during long-term GnRH therapy. Of the remaining 17 patients, two had severe cryptorchidism and failed to achieve significant testicular growth with

Table III. Symptomatic changes in 14 men with IHH during prolonged GnRH administration

Symptom	*n*	%
↑ Libido and potency	14/14	100
↑ Spontaneous erections	14/14	100
↑ Testicular size	13/14	93
Appearance of an ejaculate	11/14	79
↑ Facial hair	9/14	64
↓ Voice	9/14	64
Appearance of mature sperm in ejaculate	7/11	64

Modified from Crowley WF Jr, et al. Recent Prog Horm Res 1985;41:473.

GnRH, three discontinued treatment before significant growth of the testes, three had azoospermia after 8 to 18 months of therapy, three failed to submit specimens for analysis, and six had been receiving therapy less than 6 months.

The time required for appearance of sperm in the ejaculate ranged from 18 to 139 weeks after initiation of therapy and was mainly a function of the size of the pretherapy gonad. Testicular size presumably reflected the degree of seminiferous tubular maturation. Other factors correlating positively with induction of spermatogenesis included duration of therapy, adequacy of dosage, patient compliance, and the absence of cryptorchidism.

Variability of sperm counts as a function of testicular size is illustrated in Fig. 4. Note that it is uncommon to see spermatogenesis with a testicular volume of less than 8 ml. High counts may be seen in patients with smaller testes, however, and low counts may be seen in those with larger testes. This emphasizes the need for close monitoring and careful individualization of therapy.[3]

It is important to recognize that patients treated with GnRH have excellent fertility potential, in spite of subnormal sperm counts. Nine of our GnRH-deficient patients who were seeking fertility fathered eight children. Sperm counts immediately preceding the time of conception ranged from 1 to 68 million/ml, and 75% of conceptions occurred at less than 15 million/ml. The one man who desired fertility and failed to impregnate his wife had a past history of cryptorchidism.

In summary a broad spectrum of abnormal GnRH secretory patterns that underlie idiopathic hypogonadotropic hypogonadism in men has been described. These patterns range from total absence of GnRH secretion through arrested pubertal development to idiopathic loss of GnRH secretion after puberty has been completed. The various subsets of idiopathic hypogonadotropic hypogonadism may be ideal for studying the role of the hypothalamic-pituitary-gonadal axis in control of reproduction.

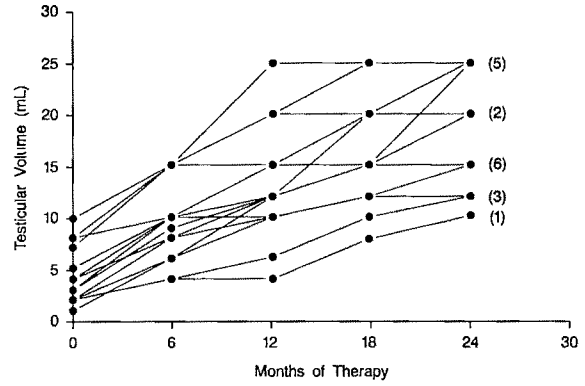

Fig. 3. Testicular growth response of 17 patients with idiopathic hypogonadotropic hypogonadism treated with pulsatile GnRH. The numbers in parentheses represent the number of individuals with that testicular volume after 24 months of pulsatile GnRH therapy. (Modified from Whitcomb RW, Crowley WF Jr. Clinical review 4: diagnosis and treatment of isolated gonadotropin-releasing hormone deficiency in men. J Clin Endocrinol Metab 1990;70:3.)

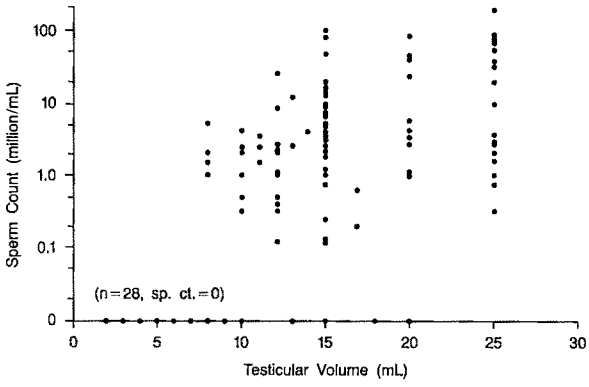

Fig. 4. Results of 128 seminal analyses in patients with idiopathic hypogonadotropic hypogonadism before and during GnRH therapy as a function of testicular volume. Of 28 samples without sperm, 20 were from patients with testicular volumes less than 9 ml. Modified from Whitcomb RW, Crowley WF Jr. Clinical review 4: diagnosis and treatment of isolated gonadotropin-releasing hormone deficiency in men. J Clin Endocrinol Metab 1990;70:3.

Patients with incomplete development of the GnRH secretory pattern may be important models for studying hypothalamic and suprahypothalamic factors influencing GnRH secretion. On the other hand, patients with no evidence of GnRH secretion provide a unique human model for studying the physiology of GnRH stimulation of the anterior pituitary gland through therapeutic administration of exogenous hormone. The information derived can make an important contribution toward greater understanding of the pathophysiology of male reproductive disorders. It may eventually help us design valuable new therapeutic and contraceptive strategies.

Clinically it has been demonstrated that one can achieve full sexual maturation in men with idiopathic hypogonadotropic hypogonadism whose pituitary-gonadal axis can be normalized by long-term administration of exogenous GnRH. Establishment of normal levels of gonadotropin and testosterone secretion is reflected in the development of masculine secondary sex characteristics, increased testicular volume and sperm count, and the induction of fertility in most patients who desire it. The potential personal and social benefits for the patient with idiopathic hypogonadotropic hypogonadism speak for themselves.

We are indebted to Denise Heavern, RN, for her dedicated care of our patients, the patients who volunteered for the studies, the General Clinical Research Center staff, and the technicians of the Reproductive Endocrine Unit.

Discussion

Audience. Do you have any explanation of why patients who have hypothalamic hypogonadism can impregnate their wives with very low sperm counts?

Dr. Crowley. I use sperm counts like school. Basically, all we have been doing for years is taking attendance, and we have not had any tests to show what they can do. Now that we have machines that can measure objective parameters, such as lateral head movement, we are going to see that there is quite a heterogeneity in those in attendance.

Audience. Have you used any of the antagonists with subsequent treatment with GnRH?

Dr. Crowley. When you give a GnRH antagonist to a human, you can suppress LH levels. At a maximal dose, where the dose-response curve of inhibition plateaus, LH is suppressed about 70% or 80%. FSH is suppressed only about 30% to 40%, and free α-subunit is suppressed about 30%. When you then give a dose of GnRH, you see a reversal of that hierarchy; you get much more LH than FSH. The doses we have used have been pharmacologic, but on the basis of the response to these doses we would assume that you would get back LH secretion, which is just what you do not want.

On the other hand, the fact that FSH is not suppressed as extensively as LH presents a potential opportunity to use another releasing factor, if one could be identified, for FSH. In other words, give the GnRH antagonist, eliminate the LH and consequent hyperandrogenemia, and then give this FSH-releasing factor, if and when such a factor is discovered.

Efficacy and safety of intravenous pulsatile gonadotropin-releasing hormone: Lutrepulse for Injection

Nanette Santoro, MD
Newark, New Jersey

A multicenter trial was undertaken to assess the ability of pulsatile gonadotropin-releasing hormone to restore physiologic ovulatory function in women with diminished or absent pulsatile gonadotropin-releasing hormone secretion. In 109 women with primary and secondary hypothalamic amenorrhea, pulsatile gonadotropin-releasing hormone (Lutrepulse [gonadorelin acetate] for Injection) was extremely effective, resulting in ovulation in 91% and 96% of patients, respectively. Overall complications of intravenous line placement ranged from 0% to 11% (mean = 7%). A 12% incidence of multiple pregnancy was noted, and a single case of ovarian hyperstimulation was reported in a woman who also received clomiphene citrate. Pulsatile gonadotropin-releasing hormone treatment appears to be of at least comparable efficacy to human menopausal gonadotropins, with the added benefit of reduced overall risks for the patient with hypothalamic amenorrhea. (Am J Obstet Gynecol 1990;163:1759-64.)

Key words: Pulsatile gonadotropin-releasing hormone, primary hypothalamic amenorrhea, secondary hypothalamic amenorrhea

Gonadotropin-releasing hormone (GnRH) is the central hypothalamic signal governing episodic secretion of pituitary gonadotropins (luteinizing hormone [LH] and follicle-stimulating hormone [FSH]). Its obligatory, permissive role in allowing the ovarian processes of folliculogenesis, ovulation, and corpus luteum function to occur was first elucidated in the subhuman primate in the early 1970s.[1] Concurrent clinical studies in women were initiated at the time that the absolute requirement for pulsatile delivery of GnRH was first being discovered.[2] Initial research in women focused on the use of long-acting analogs of GnRH that were thought to be superpotent effectors of ovulation. Unfortunately, the frequent occurrence of down-regulation of pituitary GnRH receptors often interfered with the gonadotropic effects of large doses of GnRH agonist.[3, 4]

The challenge of designing GnRH therapy for women with reproductive disorders has centered around the definition of optimal dosage, frequency, and route of administration for pulsatile administration of this hormone. Because many interspecies differences exist regarding sensitivity to pulsatile GnRH, there was little to guide initial research efforts in determining the appropriate dosage of this peptide, and the precise dosage requirements remain to be established. A useful frequency of GnRH administration in women was initially derived from the successful work in rhesus monkeys.[1] In these studies an hourly frequency of pulsatile GnRH was uniformly successful. However, close scrutiny of the human menstrual cycle[5-7] has allowed for an adjustment to a more physiologic frequency or indeed a panel of frequencies that has now been shown to be effective in adult women. Finally, the optimal route of administration of pulsatile GnRH appears to be intravenous. After an intravenous bolus, a physiologic LH pulse contour is achieved, along with superior rates of ovulation, compared with subcutaneous administration.[8-11] It has become clear, however, that in some cases the intravenous route may pose hazards to a patient,[12] and in selected cases subcutaneous use as a less effective alternative may be considered.

The clinical use of intravenous pulsatile GnRH, which led to its approval by the Food and Drug Administration in the United States, was based on patients in whom this treatment might be expected to be most effective: women with primary hypothalamic amenorrhea, an experiment of nature of near-absolute GnRH deficiency. A second group of women with secondary hypothalamic amenorrhea have also proven to ovulate and become pregnant with great success with this form of treatment, and their data have also been included in this report. Three clinical centers in the United States, along with one large clinical center in Germany, formed most of the contributing data that will be presented in the subsequent tables.[13-16] These centers are broken down and the data are described in

detail to point up their overall consistency, as well as the contribution of certain idiosyncrasies from center to center, in the overall interpretation.

Material and methods

Patient population. All women recruited from the various centers for study carried the diagnosis of hypothalamic amenorrhea. In most cases this diagnosis referred to amenorrhea of at least 6 months' duration in an individual of normal body weight. Subjects were also required to undergo a clinical examination, with findings consistent with hypothalamic amenorrhea (i.e., no evidence of hirsutism, ovarian enlargement, androgen excess, or hyperprolactinemia). In addition, a normal clinical or biochemical thyroid evaluation and documented absence of hyperprolactinemia were required. Informed consent was obtained from each subject before participation and approval by the respective internal review boards of the institutions involved was obtained. In patients recruited from some of the centers, studies to document tubal patency, semen evaluation of the male partner, and postcoital examinations were performed routinely. However, in other institutions, clinical judgment was exercised as to whether any or all of these tests were carried out.

Protocol. GnRH was administered through an intravenous pump (Zyklomat; Ferring Laboratories, Suffern, N.Y.). Details of this technique have been reported previously.[17] Briefly, all patients received intravenous GnRH (Lutrepulse [gonadorelin acetate] for Injection, Ortho Pharmaceutical Corp., Raritan, N.J.) at the dose ranges outlined in Table I. In general, ovulatory and anovulatory regimens of GnRH lasted for 1 month.

The frequency of the pulsatile GnRH infusion was uniformly 90 minutes in centers 2, 3, and 4. In center 1, a frequency of 90 or 60 minutes was used in the follicular phase, and progressive slowing of the peristaltic pump throughout the luteal phase was employed to mimic the luteal-phase slowing of normal gonadotropin pulsations.[7, 17] These alterations in frequency do not appear to have had an impact on overall pregnancy rates, although the numbers are small (Table II).

Monitoring of subjects. Subjects were monitored with daily blood sampling for LH, FSH, estradiol, and progesterone levels in some centers (1, 2, and 3). Blood samples were obtained 45 minutes after a GnRH dose. Intravenous lines were inspected visually (daily in most cases), and the course of follicular maturation was followed by a combination of (1) serial ultrasonography, (2) examinations of cervical mucus, and (3) charting of basal body temperature.

Laboratory methods. Serum samples from each subject were processed for gonadotropin and sex steroid determination, as described previously for center 1.[17] In Fig. 1 values are expressed as equivalents of the second international reference preparation of human menopausal gonadotropin (milli international units per milliliter). The interassay and intraassay coefficients of variation for FSH were 12.3% and 7.8%; corresponding values for LH were 12.5% and 5.8%.

Results

Practical clinical use of GnRH: efficacy. *Patient selection and route of administration.* The four centers discussed herein used relatively stringent criteria for patient selection. However, each center may have had slight differences in patient selection. Most of the centers employed as study subjects only those women with primary or secondary hypothalamic amenorrhea who suffered solely from an ovulatory defect and had no other contributing infertility factors. This was not true of every center; therefore, pregnancy rates would be expected to be lower in couples with multiple contributory infertility factors. Table II points out the overall clinical results from each of the four centers. Note the consistency of ovulation among all of these patients. With intravenous use, ovulation rates were routinely in excess of 90%. The route of administration of pulsatile GnRH in all of these cases was intravenous, and ancillary data from the three groups reporting on a smaller number of patients receiving subcutaneous GnRH revealed lower efficacy, as has been reported by other investigators.[18-20]

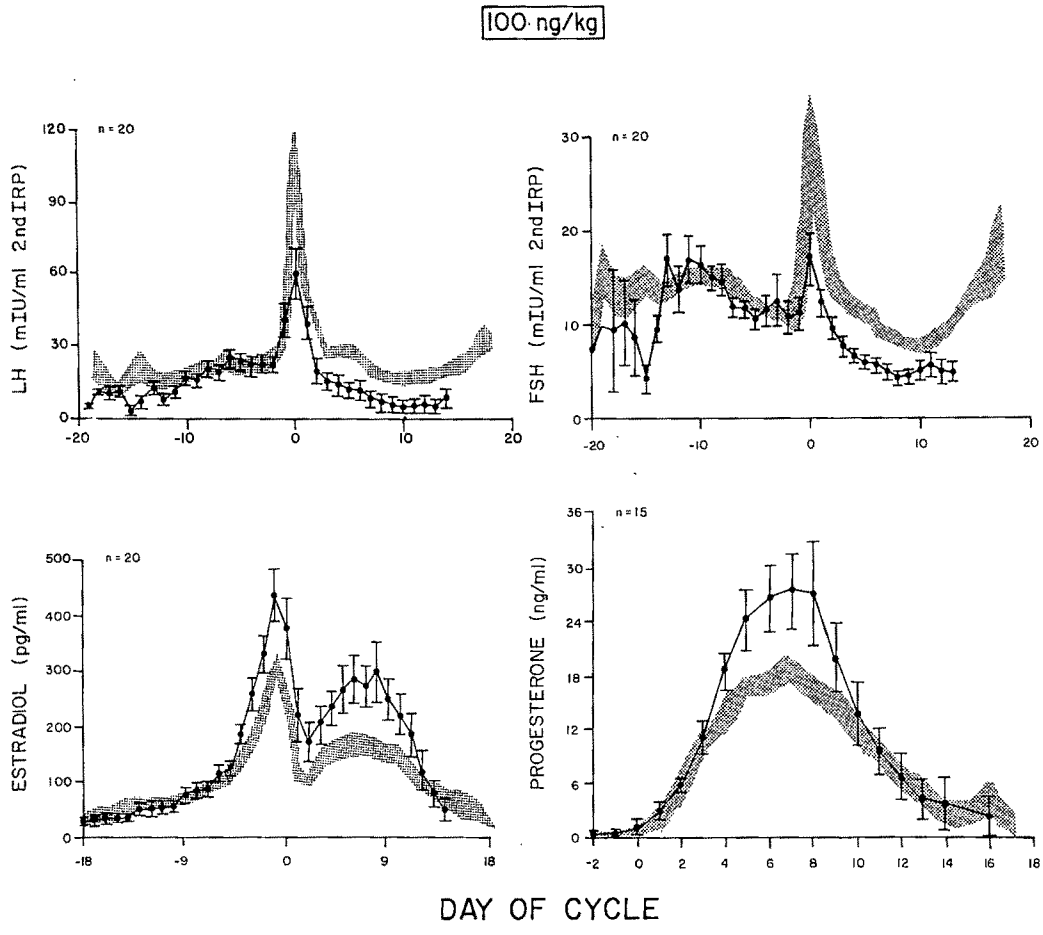

Fig. 1. Ovarian and pituitary responses to 100 ng/kg (approximately 5 μg/bolus) pulsatile GnRH in women with hypothalamic amenorrhea. Normal hormonal data are shown by the shaded background. Data are expressed as mean ± SEM and standardized to the day of the midcycle surge (day 0). The number of patients contributing data to each graph is shown in the upper left. Note that despite normal-appearing gonadotropin levels, supraphysiologic estradiol and progesterone levels were achieved. (From Santoro N, Wierman ME, Filicori M, et al. Intravenous administration of pulsatile gonadotropin-releasing hormone in hypothalamic amenorrhea: effects of dosage. J Clin Endocrinol Metab 1986;62:109.)

Frequency of pulsatile GnRH. The frequency of pulsatile GnRH used was almost uniformly 90 minutes. Group 1 used a varying frequency throughout the cycle, but the choice of a varying frequency did not seem to affect rate of ovulation (Table II). In particular, the follicular-phase frequencies employed by group 1 were 90 or 60 minutes, probably both well within the range of acceptable frequencies tolerated by the female hypothalamic-pituitary-ovarian axis.

Dose of pulsatile GnRH (Table I). The dosage of pulsatile GnRH that has proved successful varies from 1 to 20 μg/bolus. Because the exact quantity of GnRH secreted by the human hypothalamus has been difficult to determine, experimental results directed at observing sex steroid and gonadotropin secretion during pulsatile GnRH-induced cycles are most useful for deriving a physiologic dose. In 18 women studied for 30 cycles at an approximate dose of either 1 or 5 μg/bolus of GnRH, it was found that a 1 μg dose was subphysioilogic and and a 5 μg dose appeared to be slightly supraphysiologic (Fig. 1).[17] One of the other groups contributing to these data noted that at higher doses (between 10 and 20 μg/bolus) of pulsatile GnRH, pituitary and gonadal responses were exaggerated, often suggestive of multiple folliculogenesis, and engendered a higher multiple pregnancy rate of 4 per 30 conceptions.[21] Furthermore, individual sensitivity to a given

dose of pulsatile GnRH may require individualization of doses once a supposedly physiologic dosage range is derived. Thus the clinician intending to use this form of treatment will probably need to become conversant with the full dose range that will be made available.

Luteal support. Support of the corpus luteum once ovulation has been induced by pulsatile GnRH appears to be an optional matter. The varying groups used a variety of strategies to support the corpus luteum, all of which appeared equivalent, as can be seen in Table III. Thus one has the option of (1) continuing the pulsatile GnRH infusion throughout the luteal phase; (2) removing the pump as soon as the luteal phase is established (by a shift in basal body temperature, ovulation-predictor kit testing, or hormonal testing) and supplementing with human chorionic gonadotropin (hCG); or (3) employing both modalities until a missed menses, positive pregnancy test result, or menstrual period occurs.

Clinical use of pulsatile GnRH: safety of intravenous pulsatile GnRH. *Safety of the intravenous catheter.* Recent data[12] suggest that the intravenous route of GnRH administration is quite safe for prolonged periods of time. Fig. 2 shows the low incidence of positive catheter tip (11%) and blood cultures (2%) in a group of 38 women receiving long-term pulsatile GnRH with 230 catheter insertions. No clinical evidence of infection attributable to the presence of the intravenous catheter occurred in this series. A small number of cases of superficial thrombophlebitis occurred in patients from all of the four centers analyzed (Table IV). Note the overall consistency of these numbers and the absence of sepsis or major morbidity caused by the presence of the intravenous catheter. Of theoretic concern is the patient with mitral valve prolapse or an abnormal cardiac valve who might be prone to the development of bacterial endocarditis should any bacteremia occur. This theoretic concern can be avoided by careful selection of patients and evaluation of the cardiac examination and echocardiographic findings in patients with heart murmurs undergoing therapy. A woman with mitral valve prolapse with no ballooning or redundancy of the valve, who is considered at lower risk for bacteremia, may well tolerate short-term intravenous use of GnRH with hasty removal of the catheter on ovulation and luteal support with hCG without mishap. However, patients with such defects might well profit from choosing the subcutaneous route, although it will be expected to be less effective.

Table V. Lutrepulse for Injection: complications

Multiple pregnancies
- 11/89 Deliveries (12%)
- 10 Sets of twins
- 1 Set of triplets
- One from center 1 (6.9 μg/pulse: all others reported from center 4 (2.5-20 μg/pulse)

Ovarian hyperstimulation
- 1/268 Patients = 0.4%; 1/932 cycles = 0.1% (subject also received clomiphene citrate)

No patient with primary hypothalamic amenorrhea had a multiple pregnancy or ovarian hyperstimulation

Ovarian hyperstimulation. Only one patient had any clinically significant ovarian hyperstimulation, for an overall incidence of 0.4%. This was of a moderate degree and, of note, this patient had already received clomiphene citrate in conjunction with the pulsatile GnRH. Thus it is expected to be extremely unusual to observe ovarian hyperstimulation of the magnitude that was routinely noted in up to 20% of women who received exogenous human menopausal gonadotropin.[22]

Multiple pregnancy. In Table V, adverse effects of pulsatile GnRH are delineated, including the occurrence of 11 multiple pregnancies. Of these 11 pregnancies, 10 were twin gestations and 1 was a triplet gestation. Table VI points out the data from two centers con-

Table VI. Lutrepulse for Injection: follicle numbers seen on ultrasonography

cerning the number of follicles visualized on routine ultrasound examination. Note that regardless of the primary or secondary nature of the hypothalamic amenorrhea, one to four mature follicles were noted on pelvic ultrasound examination. This supraphysiologic response to pulsatile GnRH may well be an effect of individual differences in requirements for a truly physiologic dose or may reflect a general trend to deliver a supraphysiologic dose to most patients. Fig. 1 shows the pituitary and ovarian responses to an approximately 5 μg/bolus dose of pulsatile GnRH, which underscores the slightly supraphysiologic nature of even the "low-dose" 5 to 6 μg regimen.[17]

Mechanical failure. Of the four centers reporting data, only three recorded the occurrence of mechanical or equipment failure that led to difficulties with treatment (Table VII). Note that in center 4 most of the problems associated with pulsatile GnRH therapy were related to pump malfunctions and the occurrence of superficial thrombophlebitis. They reported the lowest incidence of malfunctions. In center 1 most of the technical problems reported were related to reservoir and tubing defects, not the pump itself. The incidence of superficial thrombophlebitis varies somewhat among the three groups and is perhaps related to the lack of firm criteria for superficial thrombophlebitis and the difficulty distinguishing thrombophlebitis from a simple intravenous infiltration. It is safe to say that at this point the manufacturer has paid a great deal of attention to the tubing and reservoir apparatus and this now rarely malfunctions. Thus the clinician expecting to use this equipment might expect the biggest difficulty to occur with the occasional failure of the peristaltic pump to perform properly.

Comment

Pulsatile GnRH is a therapeutic modality whose time has come. It is highly effective in inducing ovulation in women with primary and secondary hypothalamic amenorrhea and routinely induces ovulation in more than 90% of patients. In patients without ancillary infertility factors, pregnancies may be anticipated to occur within several months, and most pregnancies occur within 3 months of therapy. Supplying the hypothalamic hormone to women who appear to be selectively deficient provides a physiologic avenue for therapy that is intuitively attractive to the patient and provides excellent results in terms of single folliculogenesis, single pregnancy, and predictable outcome. In addition to its high rate of efficacy, this form of treatment appears to be very safe even for prolonged intravenous use. The pitfalls of human menopausal gonadotropin therapy, including ovarian hyperstimulation syndrome and multiple pregnancies, appear to be reduced dramatically when pulsatile GnRH is used. Further reduction in dosage and attention to the individual dosage requirements of patients may allow for further reduction of the incidence of ovarian hyperstimulation and multiple pregnancy. The clinician would do well to become acquainted with this new treatment modality, because its indications may well expand into other ovulatory reproductive disorders (e.g., polycystic ovarian syndrome) as an effective and safe alternative to the armamentarium of medications that currently exist.

Discussion

Audience. What is the minimum amount of hCG required to support the luteal phase?

Dr. Santoro. My bias is to keep the pump in throughout the luteal phase because most of the patients really want to find out as early as possible if they are pregnant. By continuing with the pump, you can get an early measurement of hCG. I do not have a great deal of experience with hCG support of the luteal phase, but I have used doses on the order of 500 IU every couple of days in other patients undergoing ovulation induction.

Audience. Would you comment on antibody formation against GnRH?

Dr. Santoro. I think there have been two reported cases of antibody formation in men, and I know of one case that was reported as a possible reaction in a woman. The duration of treatment in men is so much greater that I think they are more likely to have a problem. In addition, the peptide is so small that it seems to be only very weakly antigenic.

Audience. In the woman with hypothalamic amenorrhea who has an infantile uterus, is there any reason to consider pretreatment with estrogen for several months before starting GnRH?

Dr. Santoro. We had one such patient who was 37 years old when she began pulsatile GnRH and had received no other treatment before she started. She ovulated in 17 days, and her uterus showed remarkable growth on pelvic ultrasonography. She did not conceive in her first cycle. Perhaps Dr. Filicori would also like to comment on this.

Dr. Filicori. We have a large population with primary hypothalamic amenorrhea, and we perform ultrasonography at the beginning and during treatment. We do not pretreat these patients with estrogens, and we see the size of the uterus increase about 1 week after the initiation of pulsatile GnRH therapy. As soon as endogenous estrogen levels begin to rise, the uterus will increase in size. We have treated patients with a longitudinal uterine diameter of 5 or 6 cm; by the time they ovulate the uterus is of normal size for an ovulatory woman.

Practical aspects of pulsatile gonadotropin-releasing hormone administration

Eldon D. Schriock, MD
Memphis, Tennessee

Pulsatile administration of gonadotropin-releasing hormone represents a major advance in the treatment of anovulation in women who fail to ovulate with clomiphene citrate and is an alternative for many women who currently receive human menopausal gonadotropin. Four issues must be addressed before administering pulsatile gonadotropin-releasing hormone: (1) safety, (2) efficacy, (3) convenience, and (4) cost. Each of these issues will be affected by the three major decisions a physician makes with gonadotropin-releasing hormone therapy: (1) patient selection, (2) route of administration, and (3) dose of gonadotropin-releasing hormone. The ideal candidate for gonadotropin-releasing hormone therapy is a patient with an absence of endogenous pulsatile gonadotropin-releasing hormone, as seen in hypothalamic amenorrhea. Although women with polycystic ovarian disease can be treated with pulsatile gonadotropin-releasing hormone, a decreased ovulation rate should be expected. The route of administration, intravenous or subcutaneous, and the degree of monitoring can be tailored by the physician to fit each patient's needs. Pulsatile gonadotropin-releasing hormone therapy is a safe, effective, convenient, and economical alternative to human menopausal gonadotropin for ovulation induction in women resistant to clomiphene. (Am J Obstet Gynecol 1990;163:1765-70.)

Key words: Gonadotropin-releasing hormone, hypothalamic amenorrhea, polycystic ovarian disease, intravenous administration of gonadotropin-releasing hormone, subcutaneous administration of gonadotropin-releasing hormone

Pulsatile administration of gonadotropin-releasing hormone (GnRH) represents a major advance in the treatment of anovulation. The use of human menopausal gonadotropin (hMG), clomiphene citrate, and bromocriptine has helped many anovulatory women. Unfortunately, many women remain anovulatory or have side effects as a result of these medications. Pulsatile GnRH therapy is a new option for the treatment of women who fail to ovulate with clomiphene citrate and is an alternative for many women who currently receive hMG.[1,2]

The primary indication for pulsatile GnRH will be ovulation induction in patients who fail to respond to clomiphene citrate. Pulsatile GnRH will be especially advantageous for those patients who live a long distance from a referral center where hMG is available. Because the monitoring required and the potential risks are much less with GnRH than those encountered with hMG, the local physician will be able to administer GnRH. In situations in which hMG is being administered, candidates for pulsatile GnRH will come from those patients now receiving hMG. Today patients treated for infertility undergo ovulation induction for indications other than anovulation. Pulsatile GnRH is appropriate for some, but not all, of these indications. GnRH is appropriate for treating luteal-phase defects and poor cervical mucus and improving timing for therapeutic donor insemination. GnRH is not a good choice to induce ovarian hyperstimulation. Thus GnRH is not an alternative to hMG in those patients undergoing in vitro fertilization and gamete intrafallopian transfer cycles or patients being treated for unexplained infertility.

Pulsatile GnRH can also be used for diagnostic purposes. It can be used to differentiate pituitary from hypothalamic failure. In some patients a single bolus GnRH test will fail to stimulate a gonadotropin response until the pituitary gland has been primed with pulsatile GnRH administration. In rare cases of combined hypothalamic and ovarian failure, pulsatile GnRH therapy will unmask the ovarian failure by allowing gonadotropins to reach menopausal levels during pulsatile GnRH therapy. Because pulsatile GnRH therapy, when administered intravenously, will induce ovulation in nearly 100% of patients with hypothalamic amenorrhea, some investigators believe the diagnosis

of hypothalamic amenorrhea must be questioned in those patients who fail to respond to pulsatile GnRH.

The cause of the patient's anovulation should be evaluated thoroughly before GnRH therapy. A standard workup would include assessment of prolactin, thyroid function, luteinizing hormone (LH), follicle-stimulating hormone (FSH), and androgens. Assessment of body mass index and a progestin challenge test can be used to predict the success of GnRH therapy. The minimum infertility workup required would be semen analysis. If the patient has never been exposed to ovulation, tubal function would not need to be evaluated before GnRH therapy. The laparoscopy could be postponed until after initiation of therapy if the patient has no risk factors of tubal disease or endometriosis. It is now common practice to perform a laparoscopy before beginning hMG therapy. This particular practice is less important with pulsatile GnRH therapy, because the risks of GnRH are less than those associated with hMG.

Patient selection

The ideal candidate for GnRH therapy is a patient with an absence of endogenous pulsatile GnRH (e.g., Kallmann's syndrome). These patients respond promptly and successfully to GnRH treatment. Other examples of decreased endogenous GnRH activity are patients with hypothalamic amenorrhea caused by weight loss, exercise, and stress (Table I). Before GnRH therapy, the physician should try to reverse the cause of anovulation, if possible, by decreasing the patient's activity or increasing the patient's weight. Correction of anorexia is critical before GnRH therapy. Women with anorexia respond well to GnRH, but if the anorexia is not corrected the patient's poor diet can result in severe intrauterine growth retardation.[3] Other candidates would be patients who have decreased GnRH function as a result of surgery on hypothalamic-pituitary tumors or those patients who have had trauma to the hypothalamic-pituitary unit. The Food and Drug Administration has given approval for pulsatile GnRH administration only to those patients who carry the diagnosis of primary hypothalamic amenorrhea. Although patients with severe hypothalamic amenorrhea are the ideal candidates for GnRH therapy, milder forms of hypothalamic amenorrhea can also be treated. Patients with normal serum levels of gonadotropins, a positive progestin challenge test result, and normal weight will respond to GnRH but may have decreased rates of success. Mild forms of polycystic ovarian disease will also respond to GnRH therapy. Patients with severe cases of polycystic ovarian disease, including patients with severe obesity (body mass index of greater than 25, markedly elevated androgen levels, or elevated serum LH levels >12 mU/ml), are poor candidates for GnRH therapy.[4] Combined regimens with GnRH agonists may improve success in this group.

Choosing the GnRH alternative

When is it appropriate to put the artificial hypothalamus to work? Each physician must determine if GnRH therapy is practical for his or her office. Four issues used to make this decision are (1) safety, (2) efficacy, (3) convenience, and (4) cost. Pulsatile GnRH is definitely a safer alternative compared with hMG. When used appropriately, there is a marked decrease in the rates of hyperstimulation and multiple births. Although ovarian hyperstimulation, which results in enlarged ovaries with multiple follicles, can occur in GnRH therapy, no reports of ovarian hyperstimulation syndrome have been reported. Most of the multiple births associated with GnRH therapy have resulted from high doses of GnRH or combining the GnRH therapy with clomiphene citrate or human chorionic gonadotropin (hCG) injections. Low-dose GnRH therapy alone results in a very low multiple birth rate. The second risk of GnRH therapy is that of infection. Although phlebitis and pain at the site of intravenous injection are the most commonly reported side effects, no major complications have been reported.[5] The increased use of subcutaneous therapy will decrease this complication further. Although anti-GnRH antibodies have been reported in men and women receiving GnRH therapy, no clinical sequelae have been reported as a result of development of these antibodies.

With proper patient selection, the efficacy of pulsatile GnRH is very high. Patients with severe hypothalamic amenorrhea have an almost 100% ovulatory rate with GnRH. Patient selection is the key factor in determining the success rate of GnRH therapy.

GnRH therapy results in increased convenience for both the physician and the patient. The physician's office benefits from no need for daily monitoring of the patient. This results in a decreased need for weekend staffing. Advantages for the patients include fewer vis-

its to the office and no daily injections, venipunctures, and ultrasound examinations.

The cost to the patient will depend on several factors. The first is route of administration. The increased dose required for subcutaneous administration results in increased drug costs. The duration of therapy is dependent on the patient's diagnosis and route of administration, with subcutaneous therapy taking somewhat longer from onset of therapy to ovulation. The ultimate cost to the patient will be determined by the physician's office charges and the number of GnRH kits required to complete therapy. The largest cost savings resulting from GnRH therapy may be the decrease in multiple births, avoiding the high cost of prenatal and neonatal care for multiple gestations.

Until recently, preparation of the physician's office to administer GnRH was difficult. The equipment and supplies needed to administer GnRH were purchased from multiple vendors unaccustomed to serving the needs of the reproductive endocrinologist. Today kits containing all the essential items are available. The basic items needed for GnRH administration are (1) the pulsatile pump; (2) the set, including the GnRH, tubing, battery, belt to hold the pump, and syringes; (3) heparin for intravenous administration; and (4) an ultrasound machine for monitoring therapy. Because of the ease of GnRH administration, the starting and monitoring of pulsatile GnRH activity can be delegated to a well-trained office nurse. These tasks would include checking the injection site, refilling the pump, and changing the battery.

Before the onset of therapy, the patient must be counseled concerning the benefits and risks. This would include the issues of safety, convenience, and efficacy compared with other available alternatives. The cost should be outlined to the patient and an assessment should be made concerning insurance reimbursement. Time spent on patient education will improve the patient's experience while on the pump and decrease after-hours phone calls. It is ideal to involve the patient's spouse who can then be of help in managing the pump and also understand the purpose of the therapy. It is also helpful to actually show the patient a pump to dispel any misconceptions about the apparatus. If possible, offer the patient the name of a previous patient receiving GnRH with whom she could discuss the therapy.

Method of GnRH administration

A specific method for GnRH administration now has the approval of the Food and Drug Administration. This suggested protocol includes intravenous administration of 5 μg GnRH every 90 minutes, baseline pelvic ultrasonography to be repeated on days 7 and 14 of therapy, changing of the intravenous site every 48 hours, and the administration of GnRH throughout the luteal phase. As with many therapies, for instance hMG, there are many variations and each physician has his or her own individualized regimens. This same individuality and variability has been and is currently practiced by physicians around the world who have administered pulsatile GnRH for the past 10 years.[4]

Table II. Pulsatile GnRH therapy: route of administration

	Intravenous	*Subcutaneous*
Advantages	Greater efficacy	Easy to use
Disadvantages	Infection	Larger dose

Baseline screening immediately before therapy is optional. Appropriate tests are hCG, LH, FSH, estradiol, and a baseline pelvic ultrasound examination. A progestin induction of menses is appropriate in those women who have menstrual bleeding after progestin withdrawal.

The first and most important decision to be made before GnRH therapy will be the route of administration. The controversy over intravenous versus subcutaneous administration stems from the conflicting results with subcutaneous therapy. Initial investigators found decreased success rates with subcutaneous therapy. In spite of these discouraging results, other investigators have reported continued success with subcutaneous therapy, especially when proper patient selection has been performed.[4] Differences in the pharmacokinetics between subcutaneous versus intravenous administration of GnRH have been documented in several studies. Most authors agree that peak levels of GnRH are increased with decreased time to peak and time to return to baseline with intravenous administration compared with subcutaneous administration. In spite of the differences in GnRH concentration when given subcutaneously, clinical studies indicate that in most instances the pituitary gland receives an adequate signal. A major advantage of subcutaneous therapy versus intravenous administration is the decreased risk of infectious complications. Administration of GnRH subcutaneously is much easier, especially in women in whom maintaining an intravenous line is difficult. The decreased dosage of GnRH needed with intravenous therapy may result in a significant economic benefit to patients. Other potential benefits of intravenous treatment are higher ovulatory rates and a more predictable and shorter course of therapy (Table II).

Table III. Lutrepulse for Injection: dose options

Vial (mg)	*Volume/pulse (μl)*	*Dose/pulse (μg)*
0.8	25	2.5
0.8	50	5
3.2	25	10
3.2	50	20

The dose of GnRH per pulse is becoming an increasingly important variable in pulsatile GnRH therapy. Whether a standard dose exists that is appropriate for all women is an unresolved issue. Approximately 75 ng/kg GnRH[7] will stimulate gonadotropin patterns similar to those of normal control subjects. The lowest effective dose has obvious economic advantages and may also be important in controlling the rate of multiple births. Increasing the dose per pulse will increase pregnancy rates and is probably necessary with subcutaneous therapy and in attempts to treat women with polycystic ovarian disease. Few patients ovulate with doses less than 15 μg per pulse during subcutaneous therapy. Women with polycystic ovarian disease have been treated with doses as high as 20 μg per pulse intravenously. The standard dose of administration has become 5 μg per pulse for intravenous therapy and 15 to 20 μg per pulse for subcutaneous therapy. Current packaging has resulted in four dose-per-pulse options including 2.5, 5, 10, and 20 μg per pulse (Table III). To change the dose per pulse, the concentration of GnRH in solution must be changed because the volume per pulse is fixed at either 25 or 50 μl when using Lutrepulse (gonadorelin acetate) for Injection (Ortho Pharmaceutical Corp., Raritan, N.J.) pump. Other pumps are available in which volume per pulse can be regulated.

The ideal goal of GnRH treatment would be to mimic the frequency of normal gonadotropin pulses. Perfect duplication of physiologic pulse frequency is not necessary. The standard pulse frequency is every 90 minutes. Previous studies have shown that therapy only during daytime hours can also be successful. This indicates that brief lapses in pulsatile therapy caused by equipment failure will not result in a significant decrease in efficacy.

Preparation of the pump

A solution of GnRH is made; heparin, 1000 units/ml, is added for intravenous administration. The GnRH solution is placed in a small plastic pouch or syringe that fits inside the pump. Specialized catheter systems are availabe for intravenous delivery, or standard intravenous catheters may be used. Ideally, catheters are placed into a forearm vein by a sterile technique and a surgical-type preparation of the intravenous site. A transparent dressing should be placed over the intravenous site. If placed in this manner, intravenous catheters can be left in place until patient discomfort or early signs of possible phlebitis or extravasation prompt removal with placement of the intravenous line in an alternative site. Specialized infusion sets are also available for subcutaneous administration. Small-gauge needles or a catheter can be used, with infusions most commonly placed into the lower abdominal area. Recent data indicate that placement of the subcutaneous needle in the upper arm at the base of the deltoid muscle may result in increased efficacy.[8] The needle or catheter is repositioned at another site every 3 days by either the physician or the patient.

During therapy, the only physician intervention needed is refilling the pump and checking the site of infusion. The patient can be trained to perform these tasks, especially during subcutaneous therapy. The Lutrepulse for Injection system needs to be refilled and the battery changed weekly. Ultrasound scans can be formed on days 7 and 14, and thereafter the frequency is based on the patient's response. Ultrasound monitoring during the first cycle is helpful in determining the patient's response to therapy and if changes in dose or frequency are indicated. If more than one mature follicle is visualized, it is recommended that GnRH therapy be stopped. Frequency of ultrasound monitoring can be decreased in subsequent cycles once the patient's response becomes predictable. Prediction of ovulation will help the patient time intercourse and can also be used to schedule postcoital tests. Ovulation can be detected with basal body temperature charts, LH-surge detection kits, or ultrasonography. The follicle can be expected to grow approximately 2 mm/day during the late follicular phase. After ovulation, stimulation of the corpus luteum must be maintained.

Pulsatile GnRH therapy can be continued or the pump may be stopped and injections of hCG (1000 to 2500 units intramuscularly every 3 to 4 days) used to support the luteal phase. Preliminary data indicate that continued pulsatile GnRH will result in increased efficacy and will not result in the artificial lengthening of the luteal phase that can be seen with administration of hCG. Most patients will ovulate after 10 to 20 days of GnRH therapy. A delayed response is occasionally seen in initial treatment cycles and may be explained by a need for maturation of pituitary function in women who have never gone through puberty. As therapy is continued, the length of the follicular phase will approach that of a normal cycle. Pulsatile GnRH is

maintained during the luteal phase until documentation of pregnancy by a doubling of the hCG titer or a gestational sac.

Certain questions are commonly asked by patients undergoing GnRH therapy. Patients are often concerned about disturbing the pump during sleep. Before getting into bed, the patient should remove any tape holding the tubing to the stomach or chest while leaving the tubing taped on the arm. The belt with the pump in place is removed and pinned above the pillow to the bed sheet. When bathing or showering, the pump is removed and can be hung outside the shower or tub. Almost any activity can be maintained while the patient is undergoing GnRH therapy. It is difficult to maintain complete privacy while the pump is being used. Although the pump can be covered completely by clothing, the sound of the pump cannot be muffled completely.

Potential problems during GnRH therapy include leaks from the pouch holding the fluid or in the tubing, retrograde flow of blood into the tubing, pain at the injection site, and pump failure. Ideally, a backup pump is present for pump failures, although the patient can self-administer GnRH until a replacement pump is obtained. Patients should be taught how to activate the pump, flush the intravenous line, and remove the intravenous line, in case its emergency removal is necessary. Patients receiving subcutaneous therapy can be taught how to replace the needle if the injection site becomes painful.

Failure to ovulate

In the presence of therapeutic failure, the first step should be to recheck the system and rule out equipment failure or errors in administration. Some patients will respond to an increase in the dose per pulse. Changing pulse frequency from 90 minutes to every 60 minutes may result in some increased efficacy. Some investigators continue to augment pulsatile GnRH therapy with timed hCG administration to facilitate follicular rupture or clomiphene citrate therapy.[9] These methods have been used in patients with mild polycystic ovarian disease who are poor responders to pulsatile GnRH alone. The patients should be aware that the addition of these methods to augment GnRH efficacy will also enhance the rate of multiple births.

Contraindications for pulsatile GnRH therapy

Ovarian and pituitary failure must be ruled out before GnRH therapy. Diagnosis of ovarian failure is determined by the occurrence of elevated gonadotropin levels, except in the rare instance of associated hypothalamic failure. Failure to induce LH and FSH secretion after a single bolus of GnRH is not diagnostic of pituitary failure. The pituitary gland may respond after proper GnRH "priming," which is accomplished by a few days of pulsatile GnRH therapy. Pituitary failure is one of the only disease states in which GnRH therapy is not a possible alternative to hMG. Other contraindications to GnRH therapy include a sensitivity to GnRH or uncorrected anorexia.

In summary, four issues must be addressed before the physician can decide if pulsatile GnRH will be a practical addition to the ovulation-induction regimen in his or her office: (1) safety, (2) efficacy, (3) convenience, and (4) cost. Each of these issues will be affected by the three major decisions a physician makes with GnRH therapy: (1) patient selection, (2) route of administration, and (3) dose of GnRH per pulse. Women with diagnoses other than hypothalamic amenorrhea, including polycystic ovarian disease, may be candidates for pulsatile GnRH therapy, but decreased rates of ovulation should be expected. Subcutaneous administration may prove to be the best route of therapy for initial treatment of women with hypothalamic amenorrhea, with intravenous administration being reserved for unresponsive cases. If women with polycystic ovarian disease are to be treated, GnRH should be given intravenously. Monitoring of therapeutic response with ultrasonography during treatment is needed for increased dosage regimens and in patients suspected of having endogenous GnRH activity. Pulsatile GnRH therapy is a safe, effective, convenient, and economical alternative to hMG for ovulation induction in women resistant to clomiphene.

Discussion

Audience. Would you comment on the types of needles and equipment used for both intravenous and subcutaneous delivery of pulsatile GnRH?

Dr. Schriock. For intravenous therapy, you use an angiocatheter of your choice. The pump tubing comes with a connector that will fit in a 20-gauge angiocatheter.

For subcutaneous therapy, you can use an angiocatheter or the needle set that comes with the pump kit. There are also subcutaneous kits that are used for administering insulin to diabetic patients who use insulin pumps.

FEMSTAT PREFILL

(butoconazole nitrate) VAGINAL CREAM 2%

BRIEF SUMMARY

INDICATIONS: FEMSTAT® (butoconazole nitrate) vaginal cream 2% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS: FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS: General: If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient: Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis: Animal studies have not been done.

Mutagenesis: Mutagenicity studies were negative.

Impairment of Fertility: Animal studies showed no impairment of fertility.

Pregnancy Category C: Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers: Use with caution.

Pediatric Use: Safety and efficacy have not been established.

ADVERSE REACTIONS: Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.

DOSAGE AND ADMINISTRATION: Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

CURRENT PROBLEMS IN OBSTETRICS, GYNECOLOGY AND FERTILITY

Editor-in-Chief: Robert L. Barbieri, MD
State University of
New York at Stony Brook

Current Problems in Obstetrics, Gynecology and Fertility brings you the authoritative, practical information you need to stay current in your specialty and to provide the best possible care to patients.

- Each bimonthly issue provides in-depth, monograph-length coverage (40-60 pages) of a clinical topic of vital interest to practitioners today.
- Topics are selected for relevance to your daily practice: preconceptual counseling, infertility, endocrine problems, high-risk obstetrics, diagnosis and treatment of primary and secondary amenorrhea, pediatric and adolescent gynecology, and more.
- Authors are selected for their expertise; you'll benefit from their balanced perspective on the topic and their wealth of clinical experience.
- Each article is extensively referenced, saving you hours of library research.

Variation and correlation in human fetal umbilical Doppler velocities with fetal breathing: Evidence of the cardiac-placental connection 1792
Julia H. Indik, PhD, and Kathryn L. Reed, MD
Tucson, Arizona

Changes in human fetal umbilical arterial and venous Doppler velocities during fetal breathing provide evidence of the interdependence of umbilical venous and arterial Doppler blood flow velocities and confirm the existance of the Frank-Starling mechanism in the fetal heart.

Potential prenatal predictions of Down syndrome: A statistical analysis 1796
William F. O'Brien, MD, Robert A. Knuppel, MD, MPH, Carol Torres, BS, and Deborah Sternlicht, RN, MS
Tampa, Florida

Potential predictors of Down syndrome, including α-fetoprotein, human chorionic gonadotropin, and biparietal diameter/femur length ratio, are independent measures of relative risk.

The course of labor after endurance exercise during pregnancy 1799
James F. Clapp III, MD
Burlington, Vermont

When well-conditioned women continue a high-intensity running or aerobics program throughout pregnancy, it has a beneficial effect on the course and outcome of labor.

Neonatal morphometrics after endurance exercise during pregnancy 1805
James F. Clapp III, MD, and Eleanor L. Capeless, MD
Burlington, Vermont

When a high-intensity running or aerobics program is continued during pregnancy, it produces an asymmetric pattern of growth restriction that primarily reduces neonatal fat mass.

CEFOTAN® IM/IV
(cefotetan disodium)

In intra-abdominal and gynecologic infection due to indicated organisms

For Intravenous or Intramuscular Use
BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:
Urinary tract infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri,* and *Morganella morganii*).
Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli.*
Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli.*
Gynecologic infections caused by *Staphylococcus aureus** (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus* species (excluding enterococci), *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*), *Fusobacterium* species,* and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species*).
Intra-abdominal infections caused by *E coli, Klebsiella* species (including *K pneumoniae**), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*).
Bone and joint infections caused by *Staphylococcus aureus.**
*Efficacy for this organism in this organ system was studied in fewer than ten infections.

Specimens for bacteriological examination should be obtained in order to isolate and identify causative organisms and to determine their susceptibilities to cefotetan. Therapy may be instituted before results of susceptibility studies are known; however, once these results become available, the antibiotic treatment should be adjusted accordingly.

In cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other serious infections in which the causative organism has not been identified, it is possible to use CEFOTAN concomitantly with an aminoglycoside. Cefotetan combinations with aminoglycosides have been shown to be synergistic in vitro against many Enterobacteriaceae and also some other gram-negative bacteria. The dosage recommended in the labeling of both antibiotics may be given and depends on the severity of the infection and the patient's condition.

NOTE: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycosidic antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile.* Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment or poor nutritional state, the elderly and patients with cancer. Prothrombin times should be monitored in patients at risk and exogenous vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc.) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: Although to date nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels by Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approximately 8-16 times the usual adult human dose) on days 6-35 of life (thought to be

developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approximately 2-4 times the usual human dose) only 1 of 10 treated animals was affected, and the degree of degeneration was mild.

Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies, the following adverse effects were considered related to CEFOTAN therapy.
Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).
Hematologic laboratory abnormalities occurred in 1.4% of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).
Hepatic enzyme elevations occurred in 1.2% of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).
Hypersensitivity reactions were reported in 1.2% of patients and included rash (1 in 150) and itching (1 in 700).
Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500). During postmarketing experience with CEFOTAN, anaphylactic reactions and transient thrombocytopenia have been reported.

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dosage*	Every 12 hours
10-30	Usual Recommended Dosage*	Every 24 hours
<10	Usual Recommended Dosage*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Alternatively, the dosing interval may remain constant at 12 hour intervals, but the dose reduced to one-half the usual recommended dose for patients with a creatinine clearance of 10-30 mL/min, and one-quarter the usual recommended dose for patients with a creatinine clearance of less than 10 mL/min.

When only serum creatinine levels are available, creatinine clearance may be calculated from the following formula. The serum creatinine level should represent a steady state of renal function.

$$\text{Males:} \quad \frac{\text{Weight (kg)} \times (140 - \text{age})}{72 \times \text{serum creatinine (mg/100 mL)}}$$

$$\text{Females:} \quad 0.9 \times \text{value for males}$$

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. CEFOTAN is also available in a pharmacy bulk package of 10 g in 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.

1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21); 10 g in 100 mL vial (NDC 0038-0375-10).

Does fasting interval affect the glucose challenge test? 1812
Michael D. Berkus, MD, Michael P. Stern, MD, Braxton D. Mitchell, PhD, Edward R. Newton, MD, and Oded Langer, MD
San Antonio, Texas

During pregnancy, the insulin response to a 50 mg glucose challenge is lower when patients have not eaten for ≥3 hours, as compared with a fasting interval of <3 hours.

Relationships between glucose levels and insulin secretion during a glucose challenge test 1818
Michael D. Berkus, MD, Michael P. Stern, MD, Braxton D. Mitchell, PhD, Aida Abashawl, BS, and Oded Langer, MD
San Antonio, Texas

Insulin secretion during a 50 gm glucose challenge test is related to glucose level but not to maternal size, parity, or age.

Effect of low-dose oral contraceptives on carbohydrate and lipid metabolism in women with recent gestational diabetes: Results of a controlled, randomized, prospective study 1822
Siri L. Kjos, MD, Donna Shoupe, MD, Sylvie Douyan, MD, Richard L. Friedman, MD, Gerald S. Bernstein, MD, Jorge H. Mestman, MD, and Daniel R. Mishell, Jr., MD
Los Angeles, California

Diabetes developed in women with recent gestational diabetes at a similar rate, and women had comparable lipid profiles at 6 to 13 months whether they were using low-dose oral contraceptives or a nonhormonal birth control method.

Response of placental vasculature to high glucose levels in the isolated human placental cotyledon 1828
Jonathan B. Roth, MD, James A. Thorp, MD, Sue M. Palmer, MD, Peter C. Brath, BS, Scott W. Walsh, PhD, and Sharon S. Crandell, MD
Houston, Texas

Placental vascular resistance increased in response to high levels of glucose in the isolated human placental cotyledon.

Placental thromboxane and prostacyclin production in an ovine diabetic model 1831
Jan E. Dickinson, MD, Bruce A. Meyer, MD, Peter C. Brath, BS, Susie Chmielowiec, MS, Scott W. Walsh, PhD, Valerie M. Parisi, MD, MPH, and Sue M. Palmer, MD
Houston, Texas

Streptozocin-induced ovine diabetes results in a significant reduction in the placental production rate of thromboxane and prostacyclin.

Insulin-like growth factor II and nonsuppressible insulin-like activity levels in newborns 1836
Naguib A. Samaan, MD, PhD, Pamela N. Schultz, RN, MS, and Frank K. Pham, BS
Houston, Texas

Insulin-like growth factor II appears to play a major role in fetal growth.

Growth factor activity in the blood of women in whom preeclampsia develops is elevated from early pregnancy 1839
Robert N. Taylor, MD, PhD, David C. Heilbron, PhD, and James M. Roberts, MD
San Francisco, California

A prospective, longitudinal cohort study revealed that plasma growth factor activity was elevated significantly in relation to postpartum values, as early as the first trimester, in women in whom preeclampsia eventually developed.

The effect of nifedipine therapy on fetal and placental Doppler waveforms in preeclampsia remote from term 1844
Michael M. Moretti, MD, Fiona M. Fairlie, MD, Sherif Akl, MD, Aldo D. Khoury, MD, and Baha M. Sibai, MD
Memphis, Tennessee

Oral nifedipine therapy used to reduce blood pressure in patients with preeclampsia remote from term was not associated with any adverse effects on the fetal or uteroplacental circulation as measured by the Doppler technique.

Neuroophthalmologic effects of intravenous magnesium sulfate 1848
Kathleen B. Digre, MD, Michael W. Varner, MD, and Jade S. Schiffman, MD, LTC, MC, USA
Salt Lake City, Utah, and San Francisco, California

Intravenous magnesium sulfate frequently causes visual symptoms and signs.

Low-dose aspirin
II. Relationship of angiotensin II pressor responses, circulating eicosanoids, and pregnancy outcome 1853
Charles E. L. Brown, MD, Norman F. Gant, MD, Kay Cox, MT(ASCP), Bernard Spitz, MD, Charles R. Rosenfeld, MD, and Ronald R. Magness, PhD
Dallas, Texas

Plasma eicosanoids and angiotensin II pressor responses were measured before and after low-dose aspirin therapy in normal and potentially future hypertensive pregnant women and correlated with pregnancy outcome.

Maternal and uteroplacental hemodynamic effects of chronic captopril in the hypertensive, term-pregnant rat 1861
William C. Mabie, MD, Robert A. Ahokas, PhD, and Baha M. Sibai, MD
Memphis, Tennessee

Captopril effectively lowered maternal blood pressure without adversely affecting organ and uteroplacental perfusion in the hypertensive pregnant rat.

WE HAVE A POINT TO MAKE.

SO LITTLE CAN DO SO MUCH.

The Smart Start

OVCON® 35

(norethindrone [0.4 mg] and ethinyl estradiol [0.035 mg]) tablets

Ovcon® 35 offers your patients contraception, with the lowest norethindrone dose of any combination OC. Low incidence of both androgenic side effects[1] and breakthrough bleeding.[2]

Ovcon 35 has a unique estrogen/progestogen ratio. And remember—Ovcon 35 has no generic equivalent.

Amazing how so little can do so much. Our point. Exactly.

OVCON® 35

(norethindrone [0.4 mg] and ethinyl estradiol [0.035 mg]) tablets

Indications and Usage: Ovcon is indicated for the prevention of pregnancy. Some combination products containing 35 mcg or less of ethinyl estradiol report slightly higher pregnancy rates than are reported for the higher dose combination products.

Dose-related Risk of Thromboembolism from Oral Contraceptives: Two studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of oral contraceptives be started on preparations containing 50 mcg or less of estrogen.

Contraindications: Oral contraceptives should not be used in women with any of the following conditions: 1) Thrombophlebitis or thromboembolic disorders. 2) A past history of deep vein thrombophlebitis or thromboembolic disorders. 3) Cerebral vascular or coronary artery disease. 4) Known or suspected carcinoma of the breast. 5) Known or suspected estrogen dependent neoplasia. 6) Undiagnosed abnormal genital bleeding. 7) Known or suspected pregnancy. 8) Benign or malignant liver tumor which developed during the use of oral contraceptive or other estrogen-containing products.

Warnings:

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. Women who use oral contraceptives should be strongly advised not to smoke. Use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1) *Thromboembolic Disorders and Other Vascular Problems.* An increased risk of thromboembolic and thrombotic disease associated with use of oral contraceptives is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. In a study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater. An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported. Studies conducted in the United Kingdom found that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction compared to nonusers who do not smoke. Oral contraceptive users who smoke have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. The amount of smoking is a very important factor. British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives; preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. The relative risk of thromboembolic disease associated with progestin-only oral contraceptives has not been determined. Cases of thromboembolic disease have been reported in women using progestin-only products, and they should not be presumed to be risk-free. The overall excess mortality rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15-34, 5/100,000; ages 35-44, 33/100,000; ages 45-49 140/100,000), the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. The highest risk was found in heavy cigarette smokers (15 or more cigarettes per day) who used oral contraceptives and were age 40 or older. Women who smoke should be advised not to use oral contraceptives. The use of oral contraceptives in women over age 40 with other risk factors is not recommended. The mortality associated with all of the methods of birth control is low compared to the risk of childbirth, with the exception of oral contraceptive users who smoke and are over age 40. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and for myocardial infarction is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia, and especially by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately.If feasible, oral contraceptives should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. (2) *Ocular Lesions.* There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue the medication if there is unexplained sudden or gradual, partial or complete loss of vision; sudden onset of proptosis or diplopia; papilledemia; or retinal vascular lesions, and institute appropriate diagnostic and therapeutic measures. 3) *Carcinoma.* Long term administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. In humans, one study investigated the first 21 cases of endometrial adenocarcinoma in women on oral contraceptives reported to a registry. Of those women without predisposing risk factors for this disease, nearly all occurred in women who had used a sequential oral contraceptive. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestin-only oral contraceptives. No increase in breast cancer in women taking oral contraceptives has been reported although one study reported an increased risk of breast cancer in subgroups of women treated using oral contraceptives with documented benign breast disease. There is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use oral contraceptives. 4) *Hepatic Adenoma.* Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study reported a higher risk associated with oral contraceptive formulations with high hormonal potency. Although benign and rare, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short term as well as long term users of oral contraceptives. Two studies relate the risk with duration of contraceptive use, the risk being much greater after 4 or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass, or shock. A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time. 5) *Use in Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring.* Fetal abnormalities have been reported to occur in the offspring of women who have taken progestogens and/or estrogens during pregnancy. It has been shown that females exposed in utero to diethylstibestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. A high percentage of such exposed women (30% to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Similar data are not available with the use of other estrogens but it cannot be presumed that they would not induce similar changes. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 in 1000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications and there is no evidence from well-controlled studies that progestins are effective for these uses. Increases in chromosomal aberrations have been reported in women who become pregnant soon after ceasing oral contraceptive therapy. Embryos with these anomalies are virtually always spontaneously aborted. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping oral contraceptives is unknown. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period and further use of oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed the patient should be apprised of the potential risks to the fetus and the advisability of pregnancy continuation should be discussed in light of these risks. It is also recommended that women who discontinue oral contraceptives with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend three months. Administration of progestin-only or progestin-estrogen combinations to induce withdrawal bleeding should not be used as a test for pregnancy. 6) *Gallbladder Disease.* Studies have reported an increased risk of surgically confirmed gallbladder disease appearing after one year of oral contraceptive use and doubling of the risk after 4 or 5 years of use. 7) *Carbohydrate and Lipid Metabolic Effects.* A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives. Increased serum levels of triglycerides and total phospholipids have been observed in oral contraceptive users. The clinical significance of this observation is unknown at this time. 8) *Elevated Blood Pressure.* An increase in blood pressure has been reported in women receiving oral contraceptives. The prevalence of hypertension in oral contraceptive users may be no higher than nonusers in the first year of oral contraceptive use but increases with longer exposure and in the fifth year of use is two and one-half to three times the reported prevalence in the first year. Women who previously had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. 9) *Headaches.* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of oral contraceptives and investigation of the cause. 10) *Bleeding Irregularities.* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. (11) *Ectopic Pregnancy.* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. However, in oral contraceptive failures, the ratio of ectopic to intrauterine pregnancies is higher than in women not using oral contraceptives since the drugs are more effective in preventing intrauterine rather than ectopic pregnancy. The higher ectopic-intrauterine ratio has been reported with both combination products and progestin-only oral contraceptives. 12) *Breast-Feeding.* A small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The long-range effect to the nursing infant cannot be determined at this time.

Precautions: 1) A complete medical and family history should be taken prior to the initiation of oral contraceptives. Examination should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than 1 year without another physical examination being performed. 2) Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3) Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 4) Because oral contraceptives may cause some degree of fluid retention, conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, cardiac or renal insufficiency or asthma require careful observation. 5) Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6) Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7) Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8) Serum folate levels may be depressed by oral contraceptive therapy. This may complicate subsequent pregnancy with regard to folate deficiency. 9) The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. 10) Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norephinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein -bound iodine (PBI), T_4 by column, or T_4 by radioimmunoassay. Free T_3 resin uptake is decreased, reflecting the elevated TBG, free T_4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. 11) The active yellow tablets and the inert green tablets in the 28 day regimen of Ovcon-35 contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

Information for the Patient: Detailed Patient Labeling has been prepared for use by the patient and has been made available for distribution by the pharmacist.

Drug Interactions: Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Adverse Reactions: An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see **Warnings**): Thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis; benign hepatomas; neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10% or less of patients during the first cycle (other reactions, as a general rule, are seen much less frequently or only occasionally); gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes (tenderness, enlargement, and secretion); change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; changes in corneal curvature (steepening), intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, hemolytic uremic syndrome, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erhythema nodosum, hemorrhagic eruption, vaginitis, porphyria.

Acute Overdosage: Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Induction of labor with pulsatile oxytocin 1868
Karen C. Cummiskey, MD, and M. Yusoff Dawood, MD
Louisville, Kentucky, and Houston, Texas

Pulsatile oxytocin required significantly less oxytocin and infusion fluid to induce labor and was as effective as and potentially safer than continuous oxytocin infusion.

Inhibition of spontaneous uterine contractions during the last trimester in pregnant baboons by an oxytocin antagonist 1875
Laird Wilson, Jr., PhD, Michael T. Parsons, MD, and George Flouret, PhD
Chicago, Illinois, and Tampa, Florida

An oxytocin antagonist is a potent inhibitor of spontaneous uterine contractile activity during the last trimester of pregnancy in the baboon.

Evidence of a role for protein kinase C in epidermal growth factor–induced prostaglandin E_2 synthesis in amnion cells 1883
Douglas A. Kniss, PhD, John Mershon, MD, Hsing-Chih Su, BS, Jiri Sonek, MD, Richard H. Fertel, PhD, Michael Waxman, BS, Jay D. Iams, MD, and Steven G. Gabbe, MD
Columbus, Ohio

The ubiquitous enzyme protein kinase C potentiates epidermal growth factor–induced prostaglandin E_2 synthesis and may play an important modulatory role in human amnion cell function during the onset of labor.

Lymphokine production during term human pregnancy: Differences between peripheral leukocytes and decidual cells 1890
Donald J. Dudley, MD, Murray D. Mitchell, DPhil, Kathryn Creighton, BS, and D. Ware Branch, MD
Salt Lake City, Utah

Decidual cells, morphologically resembling lymphocytes, produce significantly more granulocyte-macrophage colony-stimulating factor after stimulation than do peripheral leukocytes.

The effect of maternal hyperoxia on behavioral activity in growth-retarded human fetuses 1894
Robert Gagnon, MD, Cora Hunse, RN, and Shubnum Vijan, BSc
London, Ontario, Canada

Maternal hyperoxia produces sustained fetal breathing activity without changes in fetal heart rate or fetal body movement patterns in growth-restricted human fetuses.

Observations on the cause of oligohydramnios in prolonged pregnancy 1900
Kenneth J. Trimmer, MD, Kenneth J. Leveno, MD, Mark T. Peters, MD, and Mary Anne Kelly, RN
Dallas, Texas

Hourly fetal urine production rates were ultrasonographically measured in postterm pregnancies and found to be 50% decreased when oligohydramnios was present.

Contents continued from page 11A

A mechanism leading to reduced lung expansion and lung hypoplasia in fetal sheep during oligohydramnios 1904
Richard Harding, PhD, Stuart B. Hooper, PhD, and Kerry A. Dickson, PhD
Melbourne, Australia

The mechanism whereby oligohydramnios leads to reduced fetal lung expansion and eventual lung hypoplasia was investigated; changes in fetal posture, exacerbated by nonlabor uterine contractions, are considered to play a major role.

Soluble factors produced by isolated first-trimester chorionic villi directly inhibit proliferation of T cells 1914
Richard K. Silver, MD, Jane M. Turbov, BA, Judith A. Beaird, BS, and Joseph Golbus, MD
Evanston, Illinois

Suppression of lymphocyte transformation by chorionic villus culture supernatants suggests that soluble trophoblast factors may contribute to the survival of the fetal allograft.

Proliferative and antiproliferative effects of interferon-γ and tumor necrosis factor-α on cell lines derived from cervical and ovarian malignancies 1920
David G. Mutch, MD, L. Stewart Massad, MD, Ming-Shian Kao, MD, and John Leslie Collins, PhD
St. Louis, Missouri

Tumor necrosis factor-α and interferon-γ can stimulate or inhibit the in vitro growth of malignant cervical and ovarian cell lines; clinical responses may be similarly heterogeneous.

Distribution of CA 125 in embryonic tissues and adult derivatives of the fetal periderm 1925
Hildur Hardardottir, MD, Tim H. Parmley II, MD, J. Gerald Quirk, Jr., MD, PhD, M. Melinda Sanders, MD, Frank C. Miller, MD, and Timothy J. O'Brien, PhD
Little Rock, Arkansas

Newly developed murine monoclonal antibodies to CA 125 were used to localize antigen in formalin-fixed embryonic tissue, adult apocrine sweat glands, and mammary glands.

Comparison of norethindrone and medroxyprogesterone acetate with natural progesterone and estradiol in stimulating prolactin production from cultured endometrial stromal cells 1932
Jay H. Levin, MD, Sharon A. Tonetta, PhD, and Rogerio A. Lobo, MD
Los Angeles, California

Relative potencies of the synthetic progestins norethindrone and medroxyprogesterone acetate compared with natural progesterone, with and without estradiol, for stimulating endometrial stromal cell prolactin production are established.

"I was devastated when I found out I had genital herpes. What a relief when my doctor recommended a treatment program including Zovirax Ointment."

Zovirax® (acyclovir) Ointment 5% is an ideal complement to any treatment program for initial herpes genitalis. As clinical studies confirm, Zovirax Ointment 5% significantly lessens the duration of pain, shortens viral shedding, *and* speeds healing.[1-3]

Whenever the comfort of a topical antiviral medication is desired, prescribe Zovirax Ointment 5% for initial herpes genitalis. It suits her needs—just when she needs it most.

In initial herpes genitalis,

ZOVIRAX®
(ACYCLOVIR)
OINTMENT 5%
Antiviral Action...
Proven Results

Please see brief summary of prescribing information on next page.

References: **1.** Lacey CJN, Meaden JD, Darville JM, et al. Topical acyclovir ointment in the treatment of genital herpes simplex virus infections. *Eur J Sex Trans Dis.* 1985;2:167-170. **2.** Thin RN, Nabarro JM, Parker JD, Fiddian AP. Topical acyclovir in the treatment of initial genital herpes. *Br J Vener Dis.* 1983;59:116-119. **3.** Corey L, Benedetti JK, Critchlow CW, et al. Double-blind controlled trial of topical acyclovir in genital herpes simplex virus infections. Acyclovir symposium. *Am J Med.* 1982;73:326-334.

ZOVIRAX®
(ACYCLOVIR) OINTMENT 5%

Before prescribing, please consult full package insert, a summary of which follows:

INDICATIONS AND USAGE: Zovirax (Acyclovir) Ointment 5% is indicated in the management of initial herpes genitalis and in limited nonlife-threatening mucocutaneous Herpes simplex virus infections in immunocompromised patients. In clinical trials of initial herpes genitalis, Zovirax Ointment 5% has shown a decrease in healing time and in some cases a decrease in duration of viral shedding and duration of pain. In studies in immunocompromised patients with mainly herpes labialis, there was a decrease in duration of viral shedding and a slight decrease in duration of pain.

By contrast, in studies of recurrent herpes genitalis and of herpes labialis in nonimmunocompromised patients, there was no evidence of clinical benefit; there was some decrease in duration of viral shedding.

Diagnosis: Whereas cutaneous lesions associated with Herpes simplex infections are often characteristic, the finding of multinucleated giant cells in smears prepared from lesion exudate or scrapings may assist in the diagnosis.[1] Positive cultures for Herpes simplex virus offer a reliable means for confirmation of the diagnosis. In genital herpes, appropriate examinations should be performed to rule out other sexually transmitted diseases.

CONTRAINDICATIONS: Zovirax Ointment 5% is contraindicated for patients who develop hypersensitivity or chemical intolerance to the components of the formulation.

WARNINGS: Zovirax Ointment 5% is intended for cutaneous use only and should not be used in the eye.

PRECAUTIONS:

General: The recommended dosage, frequency of applications, and length of treatment should not be exceeded (see DOSAGE AND ADMINISTRATION). There exist no data which demonstrate that the use of Zovirax Ointment 5% will either prevent transmission of infection to other persons or prevent recurrent infections when applied in the absence of signs and symptoms. Zovirax Ointment 5% should not be used for the prevention of recurrent HSV infections. Although clinically significant viral resistance associated with the use of Zovirax Ointment 5% has not been observed, this possibility exists.

Drug Interactions: Clinical experience has identified no interactions resulting from topical or systemic administration of other drugs concomitantly with Zovirax Ointment 5%.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Acyclovir was tested in lifetime bioassays in rats and mice at single daily doses of 50, 150 and 450 mg/kg/day given by gavage. These studies showed no statistically significant difference in the incidence of benign and malignant tumors produced in drug-treated as compared to control animals, nor did acyclovir induce the occurrence of tumors earlier in drug-treated animals as compared to controls. In 2 *in vitro* cell transformation assays, used to provide preliminary assessment of potential oncogenicity in advance of these more definitive lifetime bioassays in rodents, conflicting results were obtained. Acyclovir was positive at the highest dose used in one system and the resulting morphologically transformed cells formed tumors when inoculated into immunosuppressed, syngeneic, weanling mice. Acyclovir was negative in another transformation system.

No chromosome damage was observed at maximum tolerated parenteral doses of 100 mg/kg acyclovir in rats or Chinese hamsters; higher doses of 500 and 1000 mg/kg were clastogenic in Chinese hamsters. In addition, no activity was found in a dominant lethal study in mice. In 9 of 11 microbial and mammalian cell assays, no evidence of mutagenicity was observed. In 2 mammalian cell assays (human lymphocytes and L5178Y mouse lymphoma cells *in vitro*), positive response for mutagenicity and chromosomal damage occurred, but only at concentrations at least 1000 times the plasma levels achieved in man following topical application.

Acyclovir does not impair fertility or reproduction in mice at oral doses up to 450 mg/kg/day or in rats at subcutaneous doses up to 25 mg/kg/day. In rabbits given a high dose of acyclovir (50 mg/kg/day, s.c.), there was a statistically significant decrease in implantation efficiency.

Pregnancy: *Teratogenic Effects.* Pregnancy Category C. Acyclovir was not teratogenic in the mouse (450 mg/kg/day, p.o.), rabbit (50 mg/kg/day, s.c. and i.v.) or in standard tests in the rat (50 mg/kg/day, s.c.). In a non-standard test in rats, fetal abnormalities, such as head and tail anomalies, were observed following subcutaneous administration of acyclovir at very high doses associated with toxicity to the maternal rat. The clinical relevance of these findings is uncertain.[2] There are no adequate and well-controlled studies in pregnant women. Acyclovir should not be used during pregnancy unless the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Zovirax is administered to a nursing woman.

ADVERSE REACTIONS: Because ulcerated genital lesions are characteristically tender and sensitive to any contact or manipulation, patients may experience discomfort upon application of ointment. In the controlled clinical trials, mild pain (including transient burning and stinging) was reported by 103 (28.3%) of 364 patients treated with acyclovir and by 115 (31.1%) of 370 patients treated with placebo; treatment was discontinued in 2 of these patients. Other local reactions among acyclovir-treated patients included pruritus in 15 (4.1%), rash in 1 (0.3%) and vulvitis in 1 (0.3%). Among the placebo-treated patients, pruritus was reported by 17 (4.6%) and rash by 1 (0.3%).

In all studies, there was no significant difference between the drug and placebo group in the rate or type of reported adverse reactions nor were there any differences in abnormal clinical laboratory findings.

OVERDOSAGE: Overdosage by topical application of Zovirax Ointment 5% is unlikely because of limited transcutaneous absorption (see Clinical Pharmacology).

DOSAGE AND ADMINISTRATION: Apply sufficient quantity to adequately cover all lesions every 3 hours 6 times per day for 7 days. The dose size per application will vary depending upon the total lesion area but should approximate a one-half inch ribbon of ointment per 4 square inches of surface area. A finger cot or rubber glove should be used when applying Zovirax to prevent autoinoculation of other body sites and transmission of infection to other persons. **Therapy should be initiated as early as possible following onset of signs and symptoms.**

HOW SUPPLIED: Zovirax Ointment 5% is supplied in 15 g tubes (NDC 0081-0993-94) and 3 g tubes (NDC 0081-0993-41). Each gram contains 50 mg acyclovir in a polyethylene glycol base. Store at 15°-25°C (59°-77°F) in a dry place.

A rabbit model for bacteria-induced preterm pregnancy loss 1938
Raymond A. Dombroski, MD, Donna S. Woodard, PhD, Michael J. K. Harper, PhD, and Ronald S. Gibbs, MD
San Antonio, Texas

Hysteroscopic introduction of bacteria into the uterus of preterm pregnant rabbits leads to pregnancy loss.

In vitro inhibition of esterase activity in amniotic fluid: Comparison with bacterial cultures 1944
Iffath Abbasi Hoskins, MD, Joseph Katz, PhD, Faith J. Frieden, MD, Steven A. Ordorica, MD, and Bruce K. Young, MD
New York, New York

In vitro inhibition of leukocyte esterase activity in amniotic fluid was useful in identifying specific groups of infecting organisms in chorioamnionitis.

Smoking and the antioxidant ascorbic acid: Plasma, leukocyte, and cervicovaginal cell concentrations in normal healthy women 1948
Jayasri Basu, PhD, Magdy S. Mikhail, MD, Patricia H. Payraudeau, MD, Prabhudas R. Palan, PhD, and Seymour L. Romney, MD
Bronx, New York

Comparisons were made between healthy smokers and healthy nonsmokers that revealed changes in the levels of ascorbic acid in plasma, leukocytes, and exfoliated cervicovaginal cells.

Short-term effects of smoking on the pharmacokinetic profiles of micronized estradiol in postmenopausal women 1953
Denise Lee Cassidenti, MD, Ariel G. Vijod, MS, Marcela A. Vijod, BS, Frank Z. Stanczyk, PhD, and Rogerio A. Lobo, MD
Los Angeles, California

Smoking induced changes in hepatic estrogen metabolism; this was best reflected by increased serum estrone sulfate and decreased unbound estradiol but normal estradiol and estrone in moderate smokers.

Oxytocin and vasopressin binding sites in human and bovine ovaries 1961
Anna-Riitta Fuchs, DSc, Oliver Behrens, MD, Hanns Helmer, MD, Annette Vangsted, MD, Marina Ivanisevic, MD, Jamie Grifo, MD, PhD, Ciro Barros, PhD, and Michael Fields, PhD
New York, New York, and Gainesville, Florida

Binding sites for oxytocin and vasopressin were found in human and bovine ovaries with cyclic variations that suggest a paracrine role in luteolysis and ovulation.

Contents continued from page 15A

Correlation of the testicular determinant factor sequence zinc finger Y with varying gonadal phenotypes in a series of 13 subjects with gonadal dysgenesis due to Y aneuploidy 1968

Sandra P.T. Tho, MD, Ali Behzadian, PhD, J. Rogers Byrd, PhD, and Paul G. McDonough, MD

Augusta, Georgia

Zinc finger Y was consistently identified in 4 of 13 individuals with Y aneuploidy and testicular formation; lack of testicular development in the seven remaining zinc finger Y–positive subjects may be due to single-point mutations in zinc finger Y or other pathway genes.

Isolation and characterization of the gene from a human genome encoding 17β-estradiol dehydrogenase: A comparison of Jar and BeWo choriocarcinoma cell lines 1976

Cecil A. Long, MD, Gregory S. Bauer, Mark E. Lowe, MD, PhD, Arnold W. Strauss, MD, and Michael J. Gast, MD, PhD

St. Louis, Missouri

A human gene encoding estradiol dehydrogenase was characterized and expression of this gene in choriocarcinoma cell lines was compared with that of normal cells.

Antiprogestin treatment decreases midluteal luteinizing hormone pulse amplitude and primarily exerts a pituitary inhibition 1982

Donna Shoupe, MD, Daniel R. Mishell, Jr., MD, Gregory Fossum, MD, Bradford L. Bopp, Irving M. Spitz, MD, and Rogerio A. Lobo, MD

Los Angeles, California, and New York, New York

When given in the midluteal phase, RU 486 decreases luteinizing hormone pulse amplitude, possibly through a direct pituitary effect that is not mediated through endogenous opioids.

Luteal insufficiency: Correlation between endometrial dating and integrated progesterone output in clomiphene citrate–induced cycles 1986

Bryan R. Hecht, MD, Wadi A. Bardawil, MD, Firyal S. Khan-Dawood, PhD, and M. Yusoff Dawood, MD

Chicago, Illinois, and Houston, Texas

Clomiphene citrate treatment produced true luteal phase defect as a result of significantly diminished integrated luteal phase progesterone output in only one of 19 cycles.

Specific binding sites for insulin-like growth factor I in the ovarian stroma of women with polycystic ovarian disease and stromal hyperthecosis 1992

Manubai Nagamani, MD, and Charles A. Stuart, MD

Galveston, Texas

In women with polycystic ovarian disease and hyperthecosis, the ovarian stroma has decreased binding sites for insulin but has normal concentration of insulin-like growth factor I receptors.

LAST YEAR, 4 DOCTORS GAVE UP PRIVATE PRACTICE FOR A CHALLENGING NEW CAREER.

They didn't give up medicine. They just started practicing it in a more exhilarating environment.

An environment that affords them many tangible benefits. Like a diverse practice, unlimited access to medical specialities, and financial security. Plus a lot of intangibles. Like a comfortable lifestyle, an opportunity for worldwide experiences and the respect that goes along with being an Air Force officer.

Of course, to enter an environment this rewarding, they did have to give up a few things. Like rent, equipment expenses, malpractice insurance, payrolls and utility bills.

Now, you may be intrigued by such a unique opportunity. But like any good medical professional, you'd probably like a complete case history. So call 1-800-423-USAF. Or send your curriculum vitae to Colonel William E. Patterson, United States Air Force/RSH, Randolph Air Force Base, Texas 78150-5421.

Evidence of heterogeneous mechanisms in lipoprotein lipid alterations in hyperandrogenic women 1998
Robert A. Wild, MD, Mary Bartholomew, MS, Deborah Applebaum-Bowden, PhD, Laurence M. Demers, PhD, William Hazzard, MD, and Richard J. Santen, MD
Oklahoma City, Oklahoma, Hershey, Pennsylvania, and Winston-Salem, North Carolina

Sources of hyperandrogenism in hirsute women are heterogeneous as are their lipoprotein lipid profiles; those with high luteinizing hormone/follicle-stimulating hormone ratios may have different reasons for lipid alterations.

Lectins and heparin-binding features of human spermatozoa as analyzed by flow cytometry 2006
Jaime M. Vasquez, MD, Susan F. Magargee, MS, Elaine Kunze, BA, and Roy H. Hammerstedt, PhD
Madison, Wisconsin, and University Park and Philadelphia, Pennsylvania

Flow cytometric analysis of human seminal samples detects unique characteristics of sperm surfaces.

Preembryo biopsy and analysis of blastomeres by in situ hybridization 2013
Jamie A. Grifo, MD, PhD, Ann Boyle, BS, MS, Evan Fischer, BA, Gad Lavy, MD, Alan H. DeCherney, MD, David C. Ward, PhD, and Mrinal K. Sanyal, PhD
New Haven, Connecticut

Blastomeres isolated by preembryo biopsy from mouse and human being were analyzed by in situ hybridization with chromosome- and gene-specific probes.

Factors affecting embryo implantation after human in vitro fertilization: A hypothesis 2020
Richard J. Paulson, MD, Mark V. Sauer, MD, and Rogerio A. Lobo, MD
Los Angeles, California

Pregnancy after human in vitro fertilization is dependent on embryo implantation, which is described as a function of transfer efficiency, embryo quality, and endometrial receptivity.

The Permanente Medical Group

Northern California

The Permanente Medical Group, the largest multispecialty group practice in the U.S., is undergoing explosive growth in its Northern California region: the San Francisco Bay Area, Sacramento and the Central Valley. Our rapid increase in membership has created practice opportunities throughout the region for additional BC/BE Obstetricians and Gynecologists.

Our physician-managed group is part of the comprehensive Kaiser Permanente Medical Care Program. As a TPMG physician, you have access to the latest medical technology and resources, the support of colleagues in all subspecialties — and the opportunity to provide excellent health care without the burdens of managing a practice.

Join us in one of these facilities:

Quality

Stability

Leadership

Growth

Support

Rewards

Richmond — Small, congenial clinic setting staffed by five physicians and five nurse practitioners with ready consultation for other services, including perinatology. Practice general OB/GYN, high-risk obstetrics and infertility. Expertise in colposcopy, laparoscopy, hysteroscopy and laser welcome. Resident teaching opportunities exist. Staff call at Kaiser Hospital in Oakland, shared with resident staff.

Oakland — Twenty physicians, 12 residents offer services in oncology, infertility, maternal-fetal medicine and a large ICN.

Redwood City — Specializes in family-centered maternity care; offers modern LDR rooms and full range of gynecological surgery. With ten physicians, 24-hour call is required three times each month. Beautiful Peninsula location, near San Francisco and the Pacific Ocean.

Stockton — Small four physician department in a new clinic building with new equipment, including laser. Stockton's lifestyle is affordable and attractive, offering recreational activities such as boating on the inland waterways. Centrally located, with mountains to the east and San Francisco Bay Area to the west.

Roseville — Eight physicians and two nurse practitioners in clinic setting. Patients are hospitalized for delivery and surgery in Sacramento where physicians take call for L&D and emergency about 5 times each month.

San Francisco — Full range of services including large high-risk, tertiary care OB service. Eighteen physicians, including GYN Oncologist. Residency program. Clinical research and academic teaching appointments available.

Sacramento — Growing metropolitan area between San Francisco Bay Area and Sierra Nevada mountains. Up-to-date facility with active staff of 14 and excellent residency program affiliated with the University of California at Davis. Flexible call averaging five shifts per month covers L&D, emergency room and inpatient services.

Pleasanton — Staffed by four physicians and three nurse practitioners, clinic provides general OB/GYN services, non-stress tests, ultrasound and cystoscopy. Consultant support, including a Perinatologist, readily available. Share call with staff of Walnut Creek Medical Center. Affiliated with the University of California at San Francisco as clinical instructors.

Fresno — Ground-floor opportunities in growing area for clinically-oriented individuals. Provide general OB/GYN; special interests encouraged. Planning new $26 million outpatient facility to accompany current medical office building. On call every fourth night and weekend. Local residency program at Valley Medical Center affiliated with the University of California at San Francisco. Teaching positions possible.

South San Francisco — Full service except L&D. Nine physicians, six nurse practitioners. On San Francisco Peninsula, 15 minutes from downtown.

TPMG offers many benefits: scheduled time off with cross-coverage provided by your colleagues, continuing education, malpractice insurance, a substantial retirement program and special arrangements for physicians transferring from established practice. For complete information, call or send CV to: The Permanente Medical Group, Inc., Richmond Prescott, M.D., Physician Recruitment Services, Dept. AOG-8348, 1814 Franklin, 4th Floor, Oakland, CA 94612. INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1988;108:258-65. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL.

Manuscript submission. Manuscripts should be submitted to one of the three Editors as follows:

1. **Dr. Brewer**—all manuscripts originating from the southeastern quadrant of the United States or Canada and those presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation and The Society of Perinatal Obstetricians.

2. **Dr. Zuspan**—manuscripts from the northeastern quadrant of the United States and from Japan, Israel, Italy, and England, manuscripts written for Clinical Opinion and Current Development, and Letters to the Editors. Dr. Zuspan is responsible for manuscripts from The Society of Perinatal Obstetricians. Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. Donald R. Coustan, Department of Obstetrics and Gynecology, Women and Infants Hospital of Rhode Island, 101 Dudley St., Providence, RI 02905.

3. **Dr. Quilligan**—manuscripts from the north central states (including Ohio), states west of the Mississippi River, Hawaii, Alaska, and abroad (except Japan, Israel, Italy, and England). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.

Author's designation of reviewers. When authors submit their manuscripts, they may provide the names and addresses of three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. (The Checklist and Copyright Statement may be torn from the JOURNAL or photocopied for submission.) If not completed in full, it will be returned to the author for completion.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.

Previous publication. If a report by the same author(s) has been previously published in any medium that deals in any respect whatever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. The author(s) should inform the Editor of the circumstances of the two reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and animal experimentation. It is assumed by the

Editors that manuscripts emanating from a particular institution are submitted with the approval of the requisite authority. Human experimentation that requires local institutional approval must have this approval *before the experiment is started* and approval must be so indicated in the Methods section of the submitted manuscript. Reports of experiments on animals must *state in the Methods section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed. The species of nonhuman animals used in an investigation must be named in the title, abstract, and key words of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or publisher, and the Editor(s) and publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of glossy prints of illustrations are required.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, and business and home telephone numbers of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, and business and home telephone numbers of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page and key words/phrases. On manuscript page 3 type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors.* Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Avoid duplication of text and supporting material. Emphasize

Estimating length of manuscripts

The length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A 4200-word text can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone make approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables are used, the length of the text should be adjusted accordingly.

only your important observations; do not compare your observations with those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number are allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (Ann Intern Med 1988;108:258-65). Journal titles should conform to abbreviations used in *Cumulated Index Medicus.*

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Fischermann E, Quilligan EJ, et al. Vaginal delivery following cesarean section—use of oxytocin augmentation and epidural anesthesia. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: James VHT, Folkerd EJ, Bonney RC, Beranek PA, Reed MJ. Factors influencing estrogen production and metabolism in postmenopausal women with endocrine cancer. In: van Herendael HB, Riphagen FE, Goessens L, van der Pas H, eds. The climacteric, an update. Lancaster, England: MTP Press, 1983:29.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. This signed permission must accompany the manuscript when it is submitted to the Editor. Abstracts are not acceptable as numbered references.

Illustrations and tables. Illustrations and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice.

A reasonable number of halftone and line illustrations will be reproduced without charge, but special arrangements must be made with the Editors for *color illustrations* at a cost of $525 per page (one side).

For *color photographs* submit original transparencies and two sets of unmounted prints on glossy (smooth-surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The *top, first author's last name,* and *figure number* must be indicated on the front of each transparency and the back of each print. Consistency in size of illustrations within the article is strongly preferred.

For *black-and-white illustrations* submit three sets of 3 × 4 inch (minimum) to 5 × 7 inch (maximum) unmounted, glossy photographic prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy photographic prints with good black-and-white contrast. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted.

Do not use paper clips or mar the surface of prints in any way.

Figures must be cited consecutively in the text in Arabic numerals and identified thusly on the back of the print (gummed label with): author(s) name(s), title of article, number, and top marked clearly.

Figures will be returned only on request by the author.

Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Captions should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. *If a table or any part thereof has been taken from copyrighted material, a legend to the table must give full credit to the original source.* Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Legends to illustrations. Legends for all figures must be typed double-spaced on paper separate from the text of the manuscript, and these pages must be numbered in

sequence after the references. Titles should be included in the legend, *not* on the print. Original magnifications should be provided. *If an illustration has been taken from copyrighted material, the legend must give full credit to the original source.*

Computer-generated illustrations. *Black-and-white illustrations* submitted must be legible and clearly printed in jet-black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend for the illustration should not appear on the print. On the back of each print the name of the first author and the figure number should be given and the top indicated. Original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color illustrations* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color illustrations. The preparation and submitting of color prints should follow the preceding guidelines for black-and-white computer-generated illustrations.

Permissions. Direct quotations, tables, or illustrations that have appeared in copyrighted material must be accompanied by *written permission* for their use from the copyright owner and original author along with complete information as to source. Photographs of identifiable persons must be accompanied by signed releases or else all recognizable features masked.

Requirements for special sections

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article.

Clinical Opinion. Limit of 3000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Letters to the Editors. Letters to the Editors must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words [excluding references, name(s) and address(es) of the signer(s), and the phrase "To the Editors"]. The submitted Letter to the Editors must be accompanied by a signed copyright statement. If there are two or more signers of the Letter to the Editors, one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all co-signers." These requirements apply to all types of Letters to the Editors. Letters should be sent to Dr. Zuspan.

Two types of correspondence will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie. No books will be returned.

Reprints

Reprints of articles must be obtained from the author. The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (314) 872-8370.

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms **must be completed** and sent with each submitted manuscript. If **not** completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

—The original and two copies of the manuscript are submitted.
—The appropriate signed completed checklist and assignment of copyright signed by **all** authors accompany the manuscript.
—Three sets of unmounted glossy photographic prints are submitted, properly numbered and labeled on the back of each print.
—Three sets of computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back are submitted. None are dot matrix or photographic prints.
—Human experimentation has been approved by the local institution as stated in the Methods section.
—Guidelines for the care and use of animals approved by the institution have been followed as indicated in the Methods section.
—The covering letter with essential information is with the manuscript.
—All elements of the manuscript are typed double-spaced on bond paper with 1-inch margins at top, bottom, and sides.
—All pages are numbered in the following order: title page, condensation, abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.
—Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.
—Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any co-authors that might pose a conflict of interest is described.

Previous publications

—Enclosed with the submitted manuscript are two reprints each of articles the author or co-authors have previously published or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.

Title page

—These elements are given in the following sequence, and are typed double-spaced.
—Title
—Author(s) name(s) and highest academic degree(s)
—City(ies), state(s), and country other than U.S. in which the study was conducted are given
—The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the author(s) institutional affiliation at the time of the study is indicated
—Acknowledgment of financial support is cited
—Name, address, and business and home telephone numbers of author to whom requests for reprints are to be sent
—Reprints will not be available. This has been stated on the title page
—Since the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, and business and home telephone numbers have been added
—At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract

—The abstract is typed double-spaced with required margins (on page 3) headed by the title and the author(s) name, not exceeding 150 words. For case reports and brief communications the limit of 50 words is not exceeded.
—Three to five key words or short phrases are placed beneath the abstract on page 3.

Tables

—Each table headed by a caption and numbered in Roman numerals is typed double-spaced on a separate page.
—Tables are cited in sequence in the text.

Figures

—Are numbered in Arabic numerals and are cited in numerical sequence in the text.

—Original transparencies of **color photographs** appropriately numbered and identified are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

References

—Are typed double-spaced.

—Are numbered consecutively in the order they are cited in the text.

—The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors were followed.

—Abstracts, personal communications, and unpublished work are not used as numbered references but are mentioned in the text with the written approval of the person being quoted and the signed approval is enclosed.

AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

COPYRIGHT STATEMENT

Must be signed by ALL authors

"The undersigned author(s) transfers all copyright ownership of the manuscript entitled

to Mosby–Year Book, Inc., in the event the work is published. The undersigned author(s) warrants that the article is original; is not under consideration by another publication; and its essential substance, tables, or figures have not been previously published. This restriction does not apply to abstracts or press reports published in connection with scientific meetings. The author(s) confirms the final manuscript has been read and each author's contribution has been approved by the appropriate author."

CONSULTANTS

Consultants for the American Journal of Obstetrics and Gynecology

September 1, 1989—August 31, 1990

The Editors and Mosby–Year Book, Inc., take this opportunity to acknowledge those reviewers who have contributed many hours and much effort in the evaluation of manuscripts submitted to the JOURNAL during the past year. Without their interest and help, publication of the JOURNAL would be very difficult indeed. We also continue to seek advice from reviewers and readers alike as regards their overall evaluation of the JOURNAL.

Is intrauterine transfusion associated with diminished fetal growth?

**Gregory O. Utter, MD,[a] Michael L. Socol, MD,[a] Sharon L. Dooley, MD,[a]
Scott N. MacGregor, DO,[a] and Dietra D. Millard, MD[b]**
Chicago, Illinois

Studies in animal models and human pregnancies suggest that severe fetal anemia and/or replacement of fetal with adult blood result in decreased pH, increased base deficit, and hyperlactacidemia. Similar changes have been noted in growth-retarded, nonanemic fetuses, and we therefore hypothesized that isoimmunized fetuses requiring intrauterine transfusions might have diminished growth. We longitudinally studied growth patterns in 17 isoimmunized fetuses by noting biparietal diameter and head and abdominal circumference measurements at each transfusion. The distributions of these measurements above and below the 25th, 50th, and 75th percentiles derived from our general obstetric population were compared at the initial transfusion and the last ultrasonogram performed before delivery. Birth weights also were noted and their distribution around the 25th, 50th, and 75th percentiles was compared to the expected distribution. For each ultrasonographic parameter, the distribution of measurements at the last ultrasonogram before delivery was not significantly different from the distribution at the initial ultrasonogram. The birth weight distribution also was not significantly different than the expected distribution. Thus we were unable to demonstrate slowing of fetal growth in our severely isoimmunized pregnancies. (Am J Obstet Gynecol 1990;163:1781-4.)

Key words: Fetal anemia, intrauterine transfusion, diminished fetal growth

Hyperlactacidemia and increased base deficit have been detected in umbilical cord blood on nonanemic, growth-retarded fetuses.[1, 2] The proposed mechanism of altered fetal growth in these pregnancies is uteroplacental insufficiency, which is associated with abnormal transplacental delivery of metabolic substrates such as amino acids and glucose.[3-5] The hyperlactacidemia and increased base deficit, however, suggest that fetal growth retardation may also be secondary to reduced transplacental oxygen transport with subsequent fetal hypoxemia. High-altitude studies of fetal growth are consistent with the premise that perturbations in fetal oxygen delivery may play a role in the pathophysiology of diminished fetal growth.[6, 7]

Fetal anemia also can result in abnormal fetal oxygen delivery as a result of reduced oxygen-carrying capacity.[8] In the sheep model biochemical parameters consistent with fetal hypoxia and acidosis are noted only with severe fetal anemia,[8, 9] suggesting that the fetus can compensate for moderate anemia with an increase in oxygen extraction and thereby maintain normal oxygen consumption. On the other hand, after replacement of fetal blood with adult blood, even moderate anemia results in metabolic acidosis.[9] Comparable to the animal model, in isoimmunized human pregnancies only severely anemic fetuses show a decrease in oxygen delivery and concomitant metabolic acidosis.[10-12] However, when compared with nontransfused fetuses with similar hemoglobin levels, in those fetuses transfused with adult blood, hyperlactacidemia and increased base deficit develop, suggestive of relative hypoxia.[13]

As there are qualitative similarities in the acid-base status of nonanemic, growth-retarded fetuses and anemic, transfused isoimmunized fetuses, we hypothesized that in severely isoimmunized pregnancies the profound fetal anemia and/or replacement of fetal blood volume with adult red blood cells might be associated with diminished fetal growth.

Material and methods

Seventeen nonhydropic fetuses affected by Rh or Kell isoimmunization and requiring intrauterine intravascular transfusion were studied. Ultrasonographic biparietal diameter and head and abdominal circumfer-

ence measurements were noted at the time of each transfusion. The distributions of these measurements above and below the 25th, 50th, and 75th percentiles derived from our general obstetric population[14] were compared at the initial transfusion and the last ultrasonogram performed before delivery. Birth weight percentile was determined for each infant from Brenner's growth curve[15] and the birth weight distribution above and below the 25th, 50th, and 75th percentiles for gestational age was then compared with the expected distribution.

Measurement distributions around the 25th, 50th, and 75th percentiles were compared by means of χ^2 analysis, with Fisher's exact test where appropriate. All p values <0.05 were considered statistically significant.

Results

Obstetric and transfusion data for each patient are displayed in Table I. The mean gestational age at initial transfusion was 27.0 ± 2.8 weeks, and the mean hematocrit at the initial transfusion was 19.1% ± 5.6%. The mean number of transfusions per fetus was 3 ± 1, and the mean interval from the initial transfusion to delivery was 7.3 ± 2.5 weeks. The Kleihauer-Betke acid elution test was performed on umbilical cord blood at the time of the last transfusion or at birth and showed that in 16 of 17 fetuses <5% of red blood cells showed positive stains for fetal hemoglobin.

Figs. 1, 2, and 3 display biparietal diameter, head circumference, and abdominal circumference measurements from the ultrasonogram performed at the

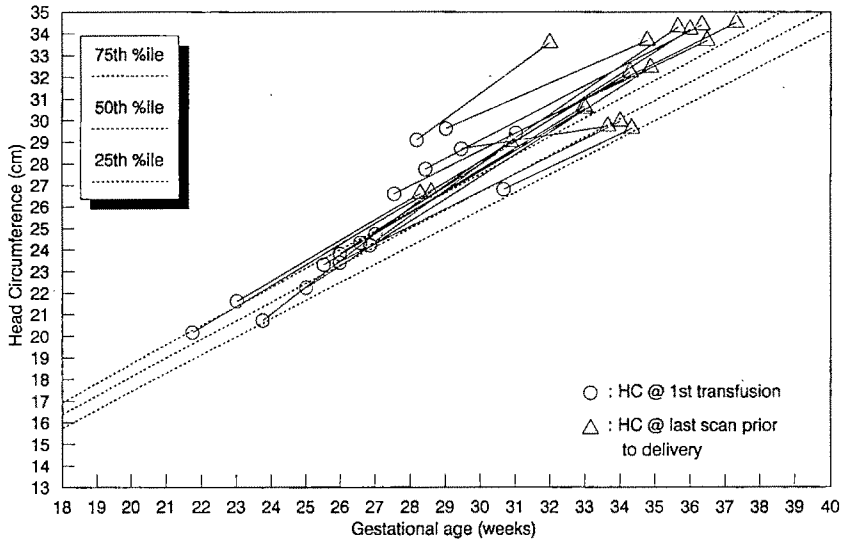

Fig. 2. Head circumference distribution at the last ultrasonogram before delivery was not different than the distribution at the initial transfusion.

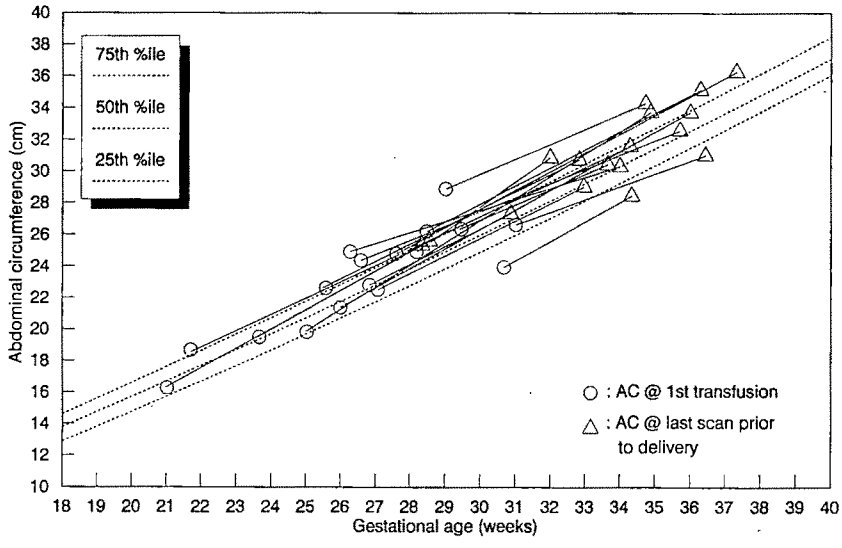

Fig. 3. Abdominal circumference distribution at the last ultrasonogram before delivery was not different than the distribution at the initial transfusion.

initial transfusion and from the last ultrasonogram before delivery, superimposed on the 25th, 50th, and 75th percentile curves derived from our general obstetric population. The distributions of the biparietal diameter, head circumference, and abdominal circumference measurements at the last ultrasonogram before delivery were not significantly different from the distributions at the initial ultrasonogram, nor were the distributions of the biparietal diameter or abdominal circumference at either ultrasonogram significantly different from that of our general obstetric population. The head circumference distribution at the final ultrasonogram revealed significantly more measurements above the 75th percentile ($\chi^2 = 5.85$, $p < 0.05$). The birth weight distribution was not significantly different from the expected distribution.

Comment

The biochemical consequences of fetal anemia and intrauterine transfusions with adult blood have been examined in animal models and in human pregnancies via umbilical vessel blood sampling. These studies consistently suggest that severe fetal anemia and/or replacement of fetal blood with adult blood result in relative hypoxia, with decreasing pH, increased base deficit, and hyperlactacidemia.[8-13] The clinical significance

of these findings is uncertain, but it has been postulated that these changes make the fetus more susceptible to hypoxia during acute stress, i.e., during labor. To our knowledge, however, no one has longitudinally studied the potential for more long-term effects of anemia and intrauterine transfusion on fetal development. We postulated that the relative hypoxia and acidemia attributable to anemia or intrauterine replacement of fetal blood with adult blood might result in diminished fetal growth.

After studying growth patterns in our 17 anemic, transfused fetuses, we were unable to demonstrate slowing of fetal growth despite nearly total replacement of fetal blood with adult red blood cells. Slowing of fetal growth after the onset and treatment of anemia would have resulted in more measurements at the final ultrasonogram being distributed below each percentile when compared with the ultrasonographic measurements at the initial transfusion. However, we found that the distribution of standard morphometric measurements around the 25th, 50th, and 75th percentiles remained unchanged over the interval from the initial transfusion to delivery and was comparable to the distribution of the general obstetric population. Also, the distribution of birth weight percentiles was not different than expected.

The fetuses in this study were severely anemic at the time of the initial transfusion, and subsequent transfusions were performed when fetal hematocrit was estimated to be 20% to 25%. Further, the interval from the first transfusion to birth was sufficiently long to allow for and enable the detection of altered intrauterine growth. Consequently, our observations suggest that alterations in oxygenation parameters that may be significant at the biochemical level are not manifested clinically by diminished fetal growth.

Prognostic indicators of the resolution of nonimmune hydrops fetalis and survival of the fetus

Dru E. Carlson, MD, Lawrence D. Platt, MD, Arnold L. Medearis, MD, and Janet Horenstein, MD

Los Angeles, California

To delineate any possible prognostic indicators, we reviewed the ultrasonographic and nonmorphometric findings in 19 antenatally diagnosed cases of nonimmune hydrops fetalis in which it was chosen to continue the pregnancy. Thirteen fetuses died and six survived. Of all parameters examined, including associated anomalies, abnormal karyotype, location of serous fluid, anemia, and possible cause of nonimmune hydrops fetalis, the most sensitive prognostic indicator was the real-time-directed M-mode echocardiographic measurement of the biventricular outer dimension in diastole. All fetuses with biventricular outer dimensions >95% died, whereas all but one with normal biventricular outer dimensions had resolution of nonimmune hydrops fetalis and survived. This was highly significant ($p < 0.001$) with the predictive value of a normal biventricular outer dimension being 86% and the predictive value of an enlarged biventricular outer dimension being 100%. (AM J OBSTET GYNECOL 1990;163:1785-7.)

Key words: Nonimmune hydrops fetalis, M-mode echocardiography, prenatal diagnosis

Nonimmune hydrops fetalis is defined as an excessive amount of total body water that results in extracellular accumulation of fluid in tissues and serous cavities. It occurs specifically without evidence of antibodies to red blood cell antigens. The ultrasonographic diagnosis of hydrops fetalis can be made by identifying two or more fluid-filled spaces within the affected fetus.[1] For example, there can be pleural effusions, pericardial effusions, ascites, and skin edema. There are more than 80 causes of this condition, and the incidence is approximately 1 in 3000 deliveries.[2, 3] The perinatal death rate is 40% to 90%.[2-4] However, some fetuses do survive. Until now there has not been a specific ultrasonographic finding that is a good predictor of perinatal prognosis. Therefore the purpose of this study was to retrospectively determine the best prognostic indicator among routine prenatal ultrasonographic measurements and observations obtained in pregnancies with nonimmune hydrops fetalis.

Methods

We reviewed all cases of prenatally diagnosed nonimmune hydrops fetalis seen in our Genetics Clinic at Women's Hospital of Los Angeles County–University of Southern California Medical Center from July 1986 to June 1989. Inclusion into the study required a living fetus at the time of diagnosis and the mother electing to continue the pregnancy after diagnosis was made. All patients were offered percutaneous umbilical blood sampling and/or amniocentesis to attempt to find a cause of the nonimmune hydrops fetalis. The usual noncardiac ultrasonographic measurements were obtained, including the biparietal diameter, circumferences of the head, chest, and abdomen, femur length, placental thickness, and amniotic fluid index. In addition, we routinely obtain real-time cardiac images and real-time-directed M-mode echocardiography on every abnormal fetus. The M-mode cursor was placed perpendicular to the interventricular septum at the level of the mitral and tricuspid valves. In this way the M-mode displays the pericardium, ventricular walls, ventricular chambers and valves, and septum. These landmarks were then measured in diastole. We specifically recorded the biventricular outer dimension (BVOD) and the biventricular inner dimension (BVID). The BVOD is measured epicardium to epicardium. The BVID is defined by the inner wall of one chamber to the inner wall of the other chamber. Thus the BVID measures the size of the chambers and septum but the walls and epicardium are excluded (Fig. 1). The M-mode echocardiographic measurements were plotted against the biparietal diameter to correlate with gestational age. Normal values are from the 5% to the 95% confidence intervals. Abnormally enlarged values are greater than the 95% confidence interval. These parameters were previously delineated at our institution by DeVore et al.[5-8]

The noncardiac morphometric measurements, all

≤95%	6*	1*

*$p < 0.001$.

nonmorphometric observations, and M-mode echocardiographic evaluations were recorded at the initial diagnosis of nonimmune hydrops fetalis.

Results

Nineteen consecutive patients met the inclusion criteria. They ranged from 22.5 to 35 weeks' gestation at the time of diagnosis. Of the 19, 6 survived and 13 died—6 in the antepartum period and 7 in the neonatal period. The causes of the 13 deaths included osteogenesis imperfecta type 2, cytomegalovirus, *Pseudomonas*, parvovirus, Noonan syndrome, and Turner syndrome. Both of the latter two cases had cystic hygroma without evidence of coarctation of the aorta. There was arthrogryposis of undetermined cause in two cases, and causes of nonimmune hydrops fetalis were unknown in four cases.

Of the six survivors, only one had a known etiology of the nonimmune hydrops fetalis—a unilateral cystic adenomatoid malformation of the lung. No other cause of nonimmune hydrops fetalis could be determined by prenatal or postnatal investigations, which included viral cultures, karyotype, electrophoresis, and parvovirus probe. Table I shows the nonmorphometric parameters observed. Statistical analysis of these nonmorphometric parameters by Fisher's exact test did not differentiate the survivors from those who died.

Two fetuses who survived had invasive procedures during the antenatal period. One had a thoracentesis and one had a paracentesis; neither had a reaccumulation of fluid in those spaces after the procedure. Four fetuses who died also had invasive procedures. One had a thoracentesis and three had paracentesis. However, all had prompt reaccumulation of fluid in that space.

When we examined our M-mode echocardiographic parameters (Table II), we found that all fetuses with enlarged BVODs died and all fetuses but one with normal BVODs lived. This was highly significant by Fisher's exact test at the level of $p < 0.001$. The sensitivity of the BVOD is 92%. The specificity is 100%. The predictive value of an enlarged BVOD is 100% and the predictive value of a normal BVOD is 86%.

The one fetus that died with a normal BVOD had

an abnormal karyotype (mos 46,XY/47,XY,+20) with severe arthrogryposis and polyhydramnios. The mosaicism was diagnosed by percutaneous umbilical blood sampling at 22.5 weeks, and this karyotype was confirmed at autopsy after the fetus died in utero at 24.5 weeks.

All fetuses with normal BVODs also had normal BVIDs. However, there was variation of the BVID in the 12 fetuses with enlarged BVODs who died. Eight of these 12 had normal BVIDs. Six of those eight had thickened ventricular walls and overall cardiac hypertrophy accounting for the enlarged BVOD. These fetuses included four with neonatal death (osteogenesis imperfecta type 2, parvovirus with endocardial fibroelastosis, and two of unknown causes) and two who died antenatally (Noonan syndrome and Turner syndrome).

The remaining two of eight fetuses with enlarged BVODs but normal BVIDs had massive pericardial effusions that resulted in apparent cardiac tamponade. One of those fetuses had arthrogryposis of unknown cause and died at <4 hours of life; the other died antenatally with nonimmune hydrops fetalis of unknown causes.

Four fetuses had enlarged BVIDs and BVODs, and they all had thin ventricular walls and dilated ventricular chambers. These included two that died neonatally (one with a *Pseudomonas* septicemia and one of unknown cause). There were two antepartum deaths (one with α-thalassemia major and one with cytomegalovirus infection).

Anemia as measured by percutaneous umbilical blood sampling or at delivery was not a major cause of the nonimmune hydrops fetalis in any of these cases. The hematocrits ranged from 32% to 55%.

Autopsy findings and/or neonatal echocardiography confirmed our M-mode echocardiographic impressions in all cases.

The six fetuses who survived presently range in age from 8 months to 2.5 years and according to their parents are progressing as well as their siblings with no apparent sequelae from the nonimmune hydrops fetalis. However, none have had formal developmental testing and school performances are pending.

Comment

Of the parameters measured in this study of prenatally diagnosed nonimmune hydrops fetalis, the BVOD of the fetal heart was the best predictor of perinatal outcome; 12 of 12 fetuses with enlarged BVODs died and 6 of 7 fetuses with normal BVODs lived.

It is interesting that several other authors have found that supraventricular tachycardia is an important cause of nonimmune hydrops fetalis.[9, 10] In this study we found no fetuses with supraventricular tachycardia as the cause of nonimmune hydrops fetalis. We believe that this may be a function of our referral pattern within an indigent population.

Also one previous study reported an association between the area and amount of accumulation of fluids and the level of fetal anemia.[11] We found no evidence of significant anemia in any of the fetuses we studied, therefore it was not a good predictor of outcome.

In summary, we found that we could not predict the outcome of prenatally diagnosed fetuses with nonimmune hydrops fetalis by usual ultrasonography and/or nonmorphometric parameters. However, an enlarged BVOD as measured by M-mode echocardiography was an excellent prognosticator of fetal death. This enlarged BVOD may reflect different places on the spectrum of cardiac failure—an overall hypertrophy of the fetal heart, a large pericardial effusion, or dilated ventricular chambers with thin walls. A normal BVOD predicted all survivors of nonimmune hydrops fetalis but one. We hypothesize that the normal BVOD measurement seen in the surviving fetuses may be indicative of a less severe or compensated cardiac failure that is commonly associated with this entity.

Sources of variability in umbilical artery systolic/diastolic ratios: Implications of the Poiseuille equation

Jeffrey W. Wright, MD, and Louis E. Ridgway, MD
San Antonio, Texas

The Poiseuille equation of fluid flow suggests that umbilical cord length and cord blood viscosity may affect resistance to flow and thus affect the systolic/diastolic ratio. In this prospective study of 40 uncomplicated term pregnancies, we sought to define the relationship of umbilical cord length and cord blood hematocrit level (as an index of viscosity) to the umbilical artery systolic/diastolic ratio. To focus on these factors, we minimized known sources of systolic/diastolic ratio variability and controlled for fetal heart rate. Linear regression revealed that fetal heart rate contributed 18% of the systolic/diastolic ratio variability. Conversely, umbilical cord length and cord blood hematocrit level were not related to umbilical artery systolic/diastolic ratio. We conclude that normal variations in cord blood hematocrit level and umbilical cord length do not significantly affect systolic/diastolic ratio. (Am J Obstet Gynecol 1990;163:1788-91.)

Key words: Doppler ultrasonography, velocimetry, vascular resistance

Doppler velocimetric measurement of umbilical artery systolic/diastolic (S/D) ratio is thought to be a measure of downstream placental resistance to blood flow. It would seem that such measurements should be very useful in the detection of patients with uteroplacental insufficiency.[1-3] However, it has proved difficult to clearly distinguish between the normal and abnormal in clinical practice.[4-7] This difficulty may be a result of variability in the measured S/D ratios that is unrelated to placental resistance. Many extraneous factors including fetal heart rate (FHR),[7-10] gestational age,[7, 11] site of insonation,[7] operator,[7] and type of Doppler device have been shown to affect the measured S/D ratio.

The Poiseuille equation delineates the factors that affect fluid flow (flow = $\Delta P \pi r^4 / 8nl$; where ΔP = pressure gradient, r = vessel radius, n = viscosity, and l = vessel length). It suggests that blood viscosity and umbilical cord length may affect umbilical artery vascular resistance. Thus these factors may affect the measured S/D ratio. The relationship of umbilical cord length and S/D ratio has not been studied. Previous studies[12, 13] have suggested that viscosity or hematocrit level may affect S/D ratio. However, the inclusion of patients with uteroplacental insufficiency and severe fetal anemia may have biased these results.

The goal of this prospective study was to define the relationship of umbilical artery S/D ratio to the umbilical cord length and cord blood hematocrit level (as an index of viscosity), while either minimizing or controlling for known sources of S/D ratio variability.

Material and methods

In this prospective study, 40 patients first seen in active labor with intact membranes were examined. Active labor was defined as regular uterine contractions with cervical dilatation of 4 to 7 cm. Patients receiving epidural anesthetic agents or analgesic drugs were excluded. Potential sources of variance in S/D ratios were minimized by: (1) selection of only normal pregnancies at 38 to 41 weeks' gestation as determined by last menstrual period and confirmed by ultrasonography; (2) use of a single examiner (J. W.) and a single Doppler device (Angioscan III, Ultrasonix, Inc., North Yonkers, N.Y.); (3) exclusion of patients with any condition associated with uteroplacental insufficiency, fetal anemia, or fetal polycythemia. FHR was measured for inclusion as an independent variable to control for its effect on S/D ratio.

Continuous-wave Doppler with a 4 mHz transducer was used to obtain all S/D ratios. Patients were examined in the recumbent position with 15° to 30° of lateral uterine displacement. Readings were taken between contractions in the absence of fetal breathing or fetal body movement. Absence of fetal movement was confirmed by a combination of real-time ultrasonography, palpation, maternal perception, and the absence of characteristic changes in the Doppler waveforms. The Doppler probe was positioned on the abdomen to obtain the best quality umbilical artery signals, as recognized by the characteristic waveform and umbilical vein flow in the opposite direction. Peak systolic and lowest diastolic frequency shifts were measured with electronic calipers; S/D ratios were then calculated with five wave-

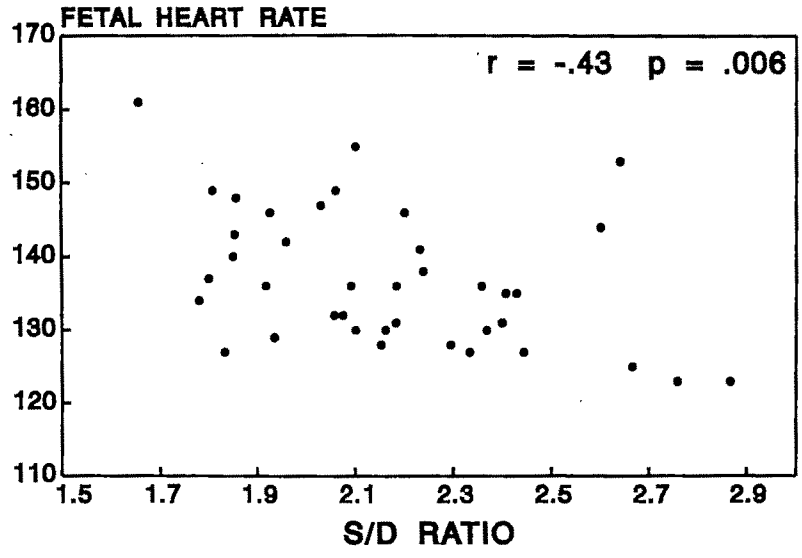

Fig. 1. Scatter plot of S/D ratio vs FHR (S/D = 4.0 − 0.013 · FHR).

forms averaged to obtain each reading. FHR was calculated by measuring the distance between waveform peaks with electronic calipers.

Umbilical cord blood was aspirated from the umbilical vein immediately after delivery and spun hematocrit obtained. Umbilical cord length was measured from fetal insertion to placental insertion with a paper tape measure.

Because S/D ratio is known to be non-normally distributed, we examined the skewness and kurtosis of the S/D ratio data and performed the Shapiro-Wilk's test for normality. We found that in this selected study population, the S/D ratios obtained were normally distributed. Thus parametric statistics were used. The three independent variables, cord length, hematocrit value, and FHR, were individually plotted against S/D ratio to assure that no nonlinear relationships existed. No nonlinear relationships were found. Individual Pearson's correlation coefficients were obtained. Multiple linear regression with all possible subsets was performed to establish the relationship between the independent variables and S/D ratio. An $\alpha < 0.05$ was used to determine significance. A biomedical data processing statistical package was used for the analysis.

Results

A total of 40 patients with a mean age of 23.8 ± 5.8 years and mean parity of 1.5 ± 1.5 were examined. All patients had normal fetal outcomes as defined by 5-minute Apgar scores >7, and normal neonatal physical examination. Table I summarizes the dependent and independent variables measured. The ranges of these variables indicate a reasonable breadth of values in our sample.

Scatter plots of S/D ratio versus FHR, cord blood hematocrit level, and umbilical cord length are displayed in Figs. 1, 2, and 3. No nonlinear relationship were found. FHR had the strongest correlation with S/D ratio ($r = -0.43$, $p = 0.006$). As expected, S/D ratio decreased as FHR increased. There was no correlation between cord blood hematocrit value and S/D ratio (Fig. 2). As seen on inspection of Fig. 3, there appears to be a slight negative correlation between S/D ratio and cord length. However, this is not statistically significant.

Table I. Summary of data obtained

	Mean ± SD	*Low*	*High*
S/D ratio	2.17 ± 0.29	1.66	2.87
Gestational age (wk)	39.6 ± 1.1	38	41
FHR (beats/min)	137.0 ± 9.2	123	161
Cord length (cm)	58.7 ± 12.9	40	95
Cord hematocrit value (%)	49.3 ± 6.2	40	67

Multiple linear regression was performed with all possible subsets. As predicted by the correlation coefficients, FHR was the only significant contributor to S/D ratio variability. Cord length and hematocrit level remained nonsignificant even after controlling for FHR with this regression. The equation obtained was S/D = 4.0 − 0.0134 × FHR ($r = 0.43$) ($p = 0.01$). The calculated r^2 of 0.18 indicates that changes in FHR account for 18% of the variability in the S/D ratio data.

To ensure that changes in S/D ratio associated with gestational age were not confounding our results, we tested the correlation of S/D ratio versus gestational age. There was no significant correlation with S/D ratio over this short span of gestational age (Spearman's rank correlation coefficient, $r = 0.002$). Further, the multi-

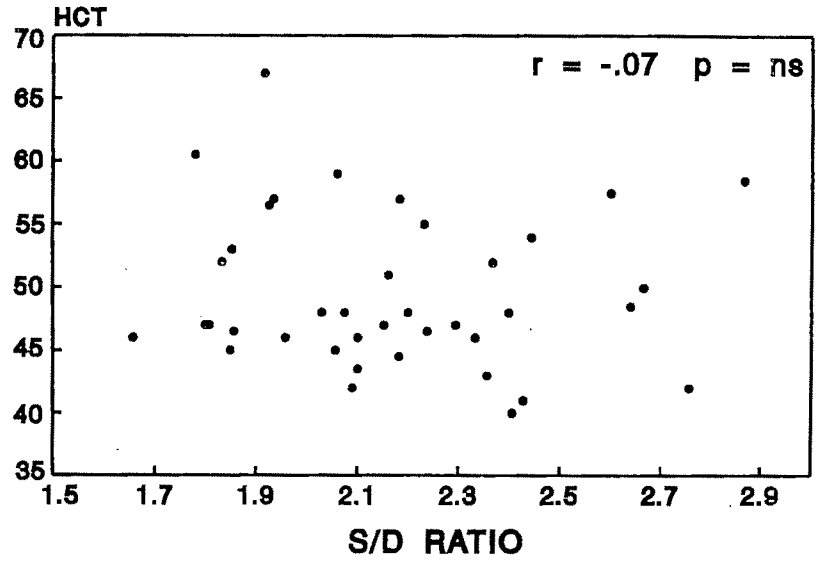

Fig. 2. Scatter plot of S/D ratio vs cord blood hematocrit value.

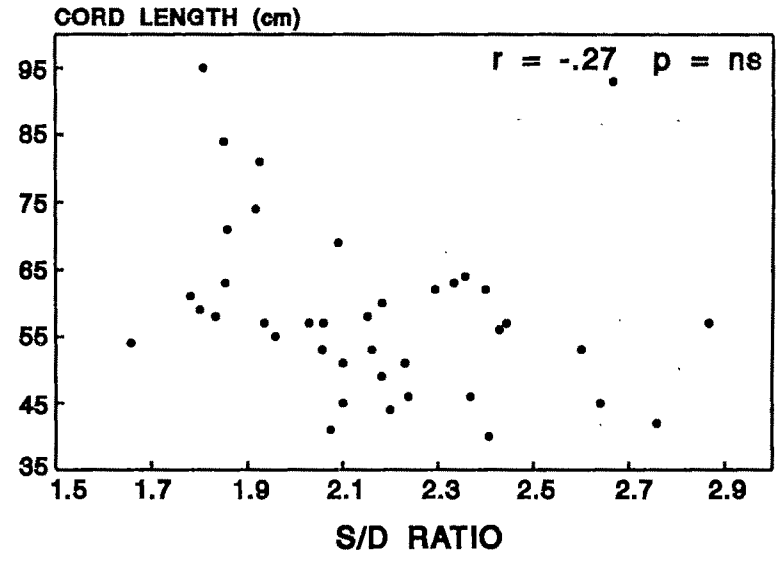

Fig. 3. Scatter plot of S/D ratio vs umbilical cord length.

ple linear regression was redone with the addition of gestational age as an independent variable. The results were unchanged.

Comment

After minimizing all other known sources of variability, we found that FHR was significantly related to S/D ratio in term pregnancies. In our study group, FHR accounted for 18% of the variability seen in the S/D ratios. We then controlled for the effect of FHR with multiple regression and were unable to show a significant relationship between S/D ratio and umbilical cord hematocrit level or umbilical cord length.

Our study confirms the findings of several previous authors[7-10] who reported that S/D ratio decreases as FHR increases. This is predictable, as slower heart rates allow the end-diastolic velocity to fall to a greater extent, resulting in a higher S/D ratio. The strength of this correlation was similar to that reported by Maulik[7] in a multivariate analysis.

In our study population, variations in hematocrit level had no relation to variation in S/D ratio. Giles and Trudinger[12] examined the relationship of S/D ratio to umbilical cord blood hematocrit level and viscosity. They found a significantly higher hematocrit level in a group of patients with elevated S/D ratios. This group also had complications of pregnancy associated with placental insufficiency. Thus both the elevated S/D ra-

tios and the higher hematocrit levels might have been related to placental insufficiency. Another explanation might be that hematocrit level affects S/D ratio only when the hematocrit level is very high. Such high hematocrit values are sometimes seen with intrauterine hypoxemia. However, the range of hematocrit levels we encountered was similar to that of Giles and Trudinger.[12]

Rightmire and colleagues[13] studied the effect of hematocrit level on umbilical artery velocimetry in a group of isoimmunized pregnancies. They found an inverse relationship between fetal hematocrit level and blood velocity in the descending aorta. The relationship between hematocrit value and Pourcelot's index (PI = (S − D)/S) was more complex, with the most severely anemic fetuses having paradoxically high measurements. These authors believed that a lower hematocrit value causes less viscosity and less resistance to flow. The paradoxically high resistance of the severely anemic fetuses was thought to be related to capillary damage and plugging. It is not appropriate to compare Rightmire's results[13] to the current study as the ranges of hematocrits values are different (6% to 38% vs 40% to 67%). Nevertheless, our data suggest that variations in hematocrit level within the normal range do not affect S/D ratio.

The slight inverse relationship of cord length and S/D ratio is contrary to what the Poiseuille equation predicts. We recognize that S/D ratios with continuous wave Doppler are measured at a variety of sites along the umbilical cord. It is possible that we may have found cord length to be a significant contributor to S/D ratio variability had we measured consistently at the fetal insertion with a duplex Doppler system. However, we chose continuous wave Doppler because these devices are more commonly available to the clinician.

A β error is the final possible explanation for our inability to show a correlation between S/D ratio and either cord length or cord hematocrit value. Power analysis with our sample size revealed an 85% chance of detecting a correlation similar to that found between S/D ratio and FHR.

Umbilical artery velocimetry is a promising tool for evaluation of the fetus. However, its current role as a clinical test is controversial. It is logical to think that placental insufficiency states would lead to elevated placental resistance and elevated S/D ratios. However, both false-negative and false-positive findings are common. The crux of the problem may lie in determining what is normal and what is abnormal. This study and those we have cited show that many factors contribute to the variability in the measurements obtained. We agree with Maulik[7] that controlling for known sources of variability may be the next step in the clinical application of Doppler velocimetry. Our study shows that normal variations in cord blood hematocrit level and umbilical cord length do not significantly contribute to this variability.

Variation and correlation in human fetal umbilical Doppler velocities with fetal breathing: Evidence of the cardiac-placental connection

Julia H. Indik, PhD, and Kathryn L. Reed, MD
Tucson, Arizona

Doppler velocity waveforms in the human fetal umbilical vein and artery were analyzed during episodes of fetal breathing. Heart rate, systolic and diastolic velocities were measured from the umbilical artery waveform. Diastolic velocity varied the most with a mean (± SD) coefficient of variation of 16.0% ± 5.0%. The coefficient of variation of systolic velocity was 7.8% ± 2.4% and of heart rate was 5.0% ± 1.8%. We also found that umbilical arterial flow was related to umbilical venous flow, implying an interdependence between fetal cardiovascular blood flow and placental blood flow. During breathing, venous flow varies because of changes in intrathoracic pressure in the fetus. This variation in umbilical venous velocity may affect the umbilical arterial diastolic velocity through alterations in placental filling, and may affect the umbilical arterial systolic velocity through alterations in ventricular filling, which by the Frank-Starling mechanism changes stroke volume. The interdependency of umbilical venous and umbilical arterial blood flow velocities must be considered in the interpretation of the significance of umbilical artery Doppler velocity measurements. (Am J Obstet Gynecol 1990;163:1792-6.)

Key words: Human fetal cardiovascular hemodynamics, Doppler ultrasonography, umbilical artery, umbilical vein, fetal breathing

Studies of human umbilical arterial Doppler blood flow velocity waveforms have shown that relative flow velocities during diastole increase with advancing gestation in normal fetuses.[1, 2] Because umbilical arterial velocities vary with fetal breathing movements, investigators have cautioned against measurement of waveforms obtained during fetal breathing.[3] Variations in umbilical venous blood flow velocities with fetal breathing have also been reported,[3-5] and, in fact, have been proposed as a means by which to recognize the presence of fetal breathing.

Disproportionately low diastolic blood flow velocities in the umbilical artery have been associated with intrauterine growth retardation.[1-3, 6] Investigators have attributed the low diastolic blood flow velocities to increased resistance in the organ perfused by umbilical arterial blood—the placenta.

In reviewing umbilical venous and arterial waveforms obtained during fetal breathing, we noted that certain patterns of variations occurred in these waveforms and hypothesized that these patterns could be quantitated. In addition, we hypothesized that these changes would not only confirm previous reports that the Frank-Starling mechanism was operative in the fetal heart,[7] but would further show that umbilical arterial waveforms vary in association with changes in umbilical venous velocities. These findings of interdependency between umbilical venous blood flow velocities and umbilical arterial blood flow velocities introduce the importance of the fetal cardiovascular function, in addition to placental function, in the determination of the umbilical arterial Doppler velocity waveform.

Methods

Ultrasonographic studies were performed in fetuses at risk of anomalies (positive family history, possible teratogen exposure) or growth abnormalities (size-date inconsistency). Two-dimensional ultrasonographic studies of fetal anatomy, size, and amniotic fluid volume were performed with 3.5 and 5.0 MHz transducers. The presence of fetal breathing was established by two-dimensional ultrasonography before and after umbilical Doppler recordings were obtained.

Umbilical venous and arterial Doppler velocities were obtained simultaneously during episodes of fetal breathing. Doppler studies were performed with a 3.5 MHz transducer. Approval for the study was obtained from the Human Subjects Committee, and informed consent was obtained from each participating mother.

Heart rate and umbilical arterial systolic and diastolic velocities were measured from strip chart recordings. The relative contribution of variation in heart rate, systolic and diastolic velocities to overall variation in the umbilical arterial waveform, was examined.

Umbilical arterial systolic and diastolic velocities and heart rate were measured with a digitizing board, and a mean value and SD were calculated for each variable in each fetus. A coefficient of variation ([SD/mean] × 100) was then determined for each variable in each fetus. For the three variables of umbilical arterial systolic velocity, umbilical arterial diastolic velocity, and heart rate, the coefficients of variation were averaged for the group of fetuses. In addition, to determine whether increases in variation of one variable were associated with increases in variation of another variable, coefficients of variation of heart rates of individual fetuses were compared with coefficients of variation of umbilical arterial diastolic velocities of individual fetuses; similarly, heart rate variations were compared with umbilical arterial systolic velocity variations, and umbilical arterial diastolic velocity variations were compared with umbilical arterial systolic velocity variations. For each fetus, a minimum of nine cardiac cycles was measured.

The Student t test was used to compare the coefficients of variation of umbilical arterial systolic and diastolic velocities with heart rate, with significance at $p < 0.05$. Linear regression analysis was used to correlate coefficients of variation for each variable in each fetus, again with significance at $p < 0.05$.

To determine whether any correlation was present between changes in umbilical arterial and venous flow, we selected fetuses in which velocities from both artery and vein were simultaneously observed for at least one breathing cycle. Typically, breathing cycles were at least twice as long as cardiac cycles; shorter breathing cycles were not analyzed. We further restricted our analysis to areas where the venous flow varied by at least two pixels (3.0 mm) in the tracings. A two-pixel limit was the smallest whereby we could be reasonably confident that the variations were real. The two-pixel limit, the length of the breathing cycle, and the need to observe both artery and vein simultaneously limited the number of fetal tracings we could analyze to 11. This two-pixel limit was also adopted to assess variations in arterial velocities in the 11 fetuses. We identified critical points, or extrema, in umbilical venous flow velocities, namely relative minima and maxima, and measured all umbilical arterial diastolic and systolic velocities in the breathing cycle being examined. At each critical point we compared the umbilical arterial diastolic and systolic velocities in the prior cardiac cycle with those in the next cycle. We adopted the following criteria to label "next" and "prior" cycles. The "next diastole" was that umbilical arterial velocity that occurred at least one half cardiac cycle after the venous critical point. The "next systole" was that umbilical arterial systolic velocity that immediately followed the next diastole. The prior umbilical arterial diastole and systole occurred in the previous cardiac cycle. An example of the relationships between next diastole, next systole, prior diastole, and prior systole and the venous critical points is displayed in Fig. 1. We noted increases (next diastole greater than prior diastole, next systole greater than prior systole) or decreases (next diastole less than prior diastole, next systole less than prior systole) that were at least two pixels; variations less than two pixels were classified as no change (next diastole equal to prior diastole, next systole equal to prior systole). Pearson's χ^2 test of association (contingency table analysis) was used to determine the significance of the observed correlations between changes in the arterial flow velocities and venous velocity extrema.

Results

Thirty-three fetuses between 25 and 41 weeks' gestation were examined. Coefficients of variation of umbilical arterial systolic and diastolic velocities and heart rate during fetal breathing were obtained in a total of 542 cardiac cycles. No fetus had anomalies, asphyxia, or intrauterine growth retardation at birth (defined as less than 10th percentile body weight by institutional standards). Coefficients of variation measured for each of these three arterial variables are reported in Table I. Umbilical arterial diastolic velocity varied the most and heart rate the least, with diastolic variation about three times that of the heart rate and twice that of the systolic velocity. Coefficients of variation for each variable correlated significantly in individual fetuses (Table I).

Table II summarizes correlations between umbilical arterial and umbilical venous flow in 11 fetuses. Need to image an artery and vein simultaneously for more than one breathing cycle and to have a minimum two-pixel venous velocity variation restricted the number of fetuses we could examine for this correlation to these 11. Simultaneous measurements of next diastole and prior diastole were possible at 48 venous minima and 45 venous maxima, a total of 93 critical points. Umbilical arterial systolic velocities were somewhat more difficult to measure accurately; however, we were able to compare next systole and prior systole at 44 venous minima and 40 maxima, a total of 84 critical points.

Table II reveals a strong correlation between umbilical arterial and umbilical venous flow. After a minimum velocity in the umbilical vein, both diastolic and systolic umbilical arterial velocities tended to increase significantly, and after a maximum velocity in the umbilical vein, both diastolic and systolic umbilical arterial

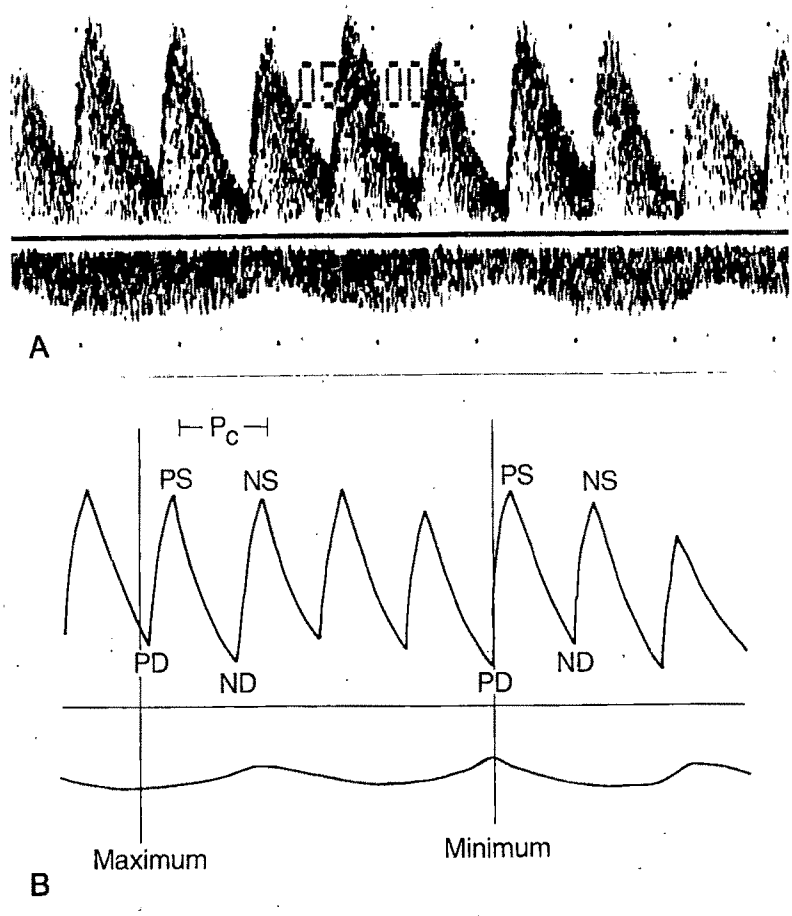

Fig. 1. A, Umbilical arterial and venous Doppler flow velocity waveforms during episode of fetal breathing. Variation in venous velocity indicates fetal respiratory changes. **B,** Diagrammatic representation of Doppler flow velocity waveforms in A, showing relationships between next diastole *(ND)*, prior diastole *(PD)*, next systole *(NS)*, and prior systole *(PS)* around maximum and minimum in venous velocity. Next diastole refers to next diastole that occurs at least one half cardiac cycle *(P_c)* after venous extremum. Next systole is systole that follows next diastole. Prior diastole and prior systole occur one cardiac cycle before next diastole and next systole, respectively. Note that next diastole is less than or equal to prior diastole and next systole is less than or equal to prior systole after venous maximum velocity, and that next diastole is greater than or equal to prior diastole and next systole is greater than or equal to prior systole after venous minimum velocity. *Horizontal dots* are 0.5 seconds apart.

Table I. Coefficients of variation in heart rate and umbilical arterial diastolic and systolic velocities during fetal breathing

	Coefficients of variation (%)
Heart rate	5.0 ± 1.8
Diastolic velocity	16.0 ± 5.0*
Systolic velocity	7.8 ± 2.4*

Heart rate vs diastolic velocity, $r = 0.58$; heart rate vs systolic velocity, $r = 0.58$; diastolic velocity vs systolic velocity, $r = 0.57$; $p < 0.001$ for all r values.

*p Value < 0.001 compared with heart rate.

velocities decreased significantly. The association was especially strong for umbilical arterial diastolic velocity (Fig. 1). There were no instances after an umbilical venous minimum in which umbilical arterial diastole decreased by at least two pixels, and no instances after an umbilical venous maximum in which umbilical arterial diastolic velocity increased by this amount. However, an increase in umbilical arterial velocity after a minimum in venous velocity, and a decrease in umbilical arterial velocity after a maximum in venous velocity were not guaranteed: the umbilical arterial diastolic change was under the two-pixel limit for 32% of the critical points. Likewise, the umbilical arterial systolic change was negligible for 43%. In fact, these instances reflect our findings that the overall variation in the umbilical arterial waveform during fetal breathing was not great, but was larger for diastole than for systole.

We assessed the significance of these correlations with a χ^2 test of association. First we tested the null hypothesis that the outcomes in which next diastole was less than prior diastole, next diastole was greater than prior

Table II. Observed correlation frequencies between umbilical venous velocity maxima and minima and umbilical arterial diastolic and systolic velocities

	Diastole			*Systole*		
	ND > PD	*ND < PD*	*ND = PD*	*NS > PS*	*NS < PS*	*NS = PS*
Minimum	37	0	11	24	5	15
Maximum	0	26	19	4	15	21

Diastole $\chi^2 = 65.0$; $p < 0.001$; systole $\chi^2 = 20.1$; $p < 0.001$.
ND, Next diastole; *PD*, prior diastole; *NS*, next systole; *PS*, prior systole.

diastole, and next diastole was equal to prior diastole were independent of being at an umbilical venous velocity minimum or maximum. We found that for umbilical arterial diastole, $\chi^2 = 65.0$. The probability of finding a χ^2 this large if the null hypothesis is correct was <0.001. The corresponding test of the null hypothesis for umbilical arterial systole gives a $\chi^2 = 20.1$ and a significance also >99.9% ($p < 0.001$).

We concluded that umbilical venous and arterial flow were not independent of each other. The trend was for umbilical arterial diastolic and systolic velocity to increase after a minimum in umbilical venous flow and to decrease after a maximum in umbilical venous flow.

Comment

We showed that heart rate and diastolic and systolic Doppler velocities in the umbilical artery vary during fetal breathing. The largest variation during breathing occurred during diastolic umbilical arterial flow. This finding of larger variations during the diastolic portion of the umbilical artery waveform, during forward flow into the placenta, suggests that compensation for alterations in blood flow related to intravascular pressure changes occurs primarily during diastole.

Furthermore, umbilical artery diastolic and systolic velocity variations correlate with phases of the breathing cycle, as reflected in the variations in umbilical venous blood flow. After a maximum in the umbilical venous velocity, both diastolic and systolic umbilical arterial velocity tended to decrease, whereas after a minimum in the umbilical venous velocity, both umbilical arterial components tended to increase. The significance of these correlations was >99.9% ($p < 0.001$) for both diastole and systole in the umbilical artery.

These results suggest that the circulation between fetus and placenta should be viewed as an interdependent system. Changes in velocity of venous blood flow returning to the fetus affect the arterial flow velocity returning to the placenta and vice versa. During breathing, the fetal intrathoracic pressure varies, and studies in instrumented fetal lambs showed that decreases in intratracheal pressure are associated with increases in blood flow in the superior and inferior vena cava.[8]

Because the velocity of umbilical venous blood flow is determined by the pressure difference between placenta and fetus, a change in intrathoracic pressure will affect umbilical venous flow. We speculate that an alteration in umbilical venous flow affects both ventricular and placental filling. When umbilical venous flow is increasing (after a minimum in umbilical venous velocity), the ventricles fill more, and by the Frank-Starling mechanism, the heart ejects more blood with a resultant increase in umbilical arterial systolic velocity.[7] Furthermore, as more blood empties from the placenta into the fetus (again after a minimum in umbilical venous velocity), the placental blood volume (and presumably pressure) will decrease. Umbilical arterial diastolic flow into the placenta then increases. After a maximum in venous velocity, umbilical venous flow velocity decreases, and umbilical arterial systolic velocity decreases because of decreased ventricular filling. Umbilical arterial diastolic velocity also decreases, probably as a result of the more-filled state of the placenta and its consequent higher pressure.

Secondary effects may serve to moderate the overall variation in umbilical Doppler velocities. For instance, increased umbilical arterial diastolic flow fills the placenta and increases its pressure, which should in turn slow umbilical arterial diastolic flow. In addition, increased umbilical venous flow empties the placenta and decreases its pressure, which in turn slows the umbilical venous flow because flow results from a differential in pressure.

Variations of umbilical arterial systolic and diastolic velocities of 5.4% to 21% (Table I) were apparently well-tolerated, inasmuch as all fetuses were normal at birth. The fact that variations in umbilical arterial blood flow velocities are associated with variations in umbilical venous blood flow velocities suggests that the placenta must be viewed not only as an organ of resistance, but also as an organ through which intrathoracic (and intracardiac) pressure changes may be transmitted.

In summary, human fetal umbilical arterial velocities vary during fetal breathing, with the largest variation during diastole. Furthermore, human fetal umbilical venous and arterial Doppler velocities are interdependent, as shown by changes that occur during presumed variations in intrathoracic pressure with fetal breathing. These changes in velocity are compatible with pressure transmission through the placenta, and, in addition, confirm the existence of the Frank-Starling mechanism in the fetal heart. The interdependency of umbilical

venous and arterial velocities must be considered in the interpretation of the changes in umbilical arterial systolic and diastolic velocities reported in fetuses with growth retardation.

Potential prenatal predictions of Down syndrome: A statistical analysis

William F. O'Brien, MD, Robert A. Knuppel, MD, MPH, Carol Torres, BS, and Deborah Sternlicht, RN, MS

Tampa, Florida

To determine the feasibility of combining several screening tests for the prenatal detection of Down syndrome, we evaluated the potential relationship among three proposed predictors. We determined the concentration of chorionic gonadotropin in frozen serum samples from women of known maternal age and weight, fetal biparietal diameter, and femur length, and α-fetoprotein concentration. When corrected for gestational age and maternal weight, the potential predictors were independent, except for a slight correlation (r = 0.10) between maternal serum α-fetoprotein and maternal serum human chorionic gonadotropin. Both maternal serum human chorionic gonadotropin and biparietal diameter/femur length demonstrated an approximately log-normal distribution similar to maternal serum α-fetoprotein. Therefore it is scientifically sound to use any or all of these variables in combination for the identification of pregnancies at increased risk for Down syndrome. (AM J OBSTET GYNECOL 1990;163:1796-8.)

Key words: Prenatal diagnosis, Down syndrome, α-fetoprotein

Because recognition of the association of fetal Down syndrome with a low maternal serum α-fetoprotein (AFP), a number of investigators have demonstrated the feasibility of the combined use of maternal age and maternal serum AFP concentration for the selection of women at increased risk for Down syndrome. In addition to maternal serum AFP, several potential markers for Down syndrome have been proposed. Of these, the concentration of human chorionic gonadotropin (hCG) in maternal serum[1] and the fetal biparietal diameter/femur length ratio[2] seem to be the most promising. Because the bayesian analysis of risk requires that assignment of final risk can only be achieved if the indicators of relative risk are independent, we sought to determine whether these proposed markers were independent of each other and of maternal age, and to examine the distribution of values in normal pregnancies.

Material and methods

Specimens were obtained from frozen samples stored at −70° C. These samples had been submitted to the

University of South Florida Regional Screening Program from Jan. 1, 1987, through Dec. 31, 1988. The following criteria were required for choice of samples: ultrasonographic measurement of biparietal diameter and femur length performed on the day of serum sampling, menstrual dating agreeing within 10 days of ultrasonographic dating, and gestational age between 15 and 19 completed weeks. When these criteria were met in more than 200 samples for a given gestational week, every other sample was chosen. Maternal age and ultrasonographic measurements, as well as assurance that the infant was phenotypically normal, were provided by the referring physician. Both maternal serum AFP and hCG concentrations were measured by enzyme-linked immunosorbent assay with commercially available kits (Abbott Laboratories, Abbott Park, Ill.). Determinations were made in duplicate and the coefficient of variation was required to be <10%. For convenience in comparison, results for maternal serum AFP were expressed as international units per ml and maternal serum hCG was expressed as international units per liter.

Samples were grouped according to completed gestational weeks and weekly medians for maternal serum AFP, and maternal serum hCG, and biparietal diameter/femur length ratios were determined. Smoothed medians were then calculated by weighted linear regression. Adjustment of maternal serum AFP and maternal serum hCG for variation in maternal weight was by regression of the nonadjusted multiples of the median with reported maternal weight. All analyses were accomplished with the SAS statistical packages (SAS Institute, Cary, N. C.).

Results

There was no correlation between maternal age and any of the three variables, either as uncorrected values or after transformation. Initial analysis confirmed the expected correlations between gestational age and maternal serum AFP ($r = 0.23$), maternal serum hCG ($r = -0.25$), and biparietal diameter/femur length ratio ($r = -0.33$). Smoothed weekly medians for each variable were generated (Table I) and values were transformed into multiples of the median. This transformation nullified an association with gestational age. However, a significant positive correlation remained between maternal serum hCG and maternal serum AFP ($r = 0.15$). Because maternal serum AFP ($r = -0.18$) and maternal serum hCG ($r = -0.23$) were both varied inversely with maternal weight, both were subsequently expressed as weight-adjusted multiples of the median. After this transformation, there was no longer a correlation with maternal weight, but a small ($r = 0.10$) but statistically significant correlation between maternal serum AFP and maternal serum hCG remained (Table II). Logarithms of maternal serum hCG multiples of the median closely approximated gaussian distribution with a Shapiro-Wilk statistic value of 0.98, whereas maternal serum AFP achieved a value of 0.96 (values may range from 0 to 1.0; 1.0 indicates completely normal distribution). The distribution of biparietal diameter/femur length with a value of 0.88 differed more from a completely normal distribution value of 0.88, but conformed sufficiently to allow clinical usage.

Table I. Smoothed weekly medians for possible screening parameters

Week	*n*	*Maternal serum AFP*	*Maternal serum hCG*	*BPD/FL*
15	76	24.1	25.0	1.73
16	146	29.4	21.0	1.66
17	130	34.7	17.0	1.60
18	120	40.4	12.7	1.53

BPD/FL, Fetal biparietal diameter/femur length ratio.

Table II. Relationship between predictors of Down syndrome

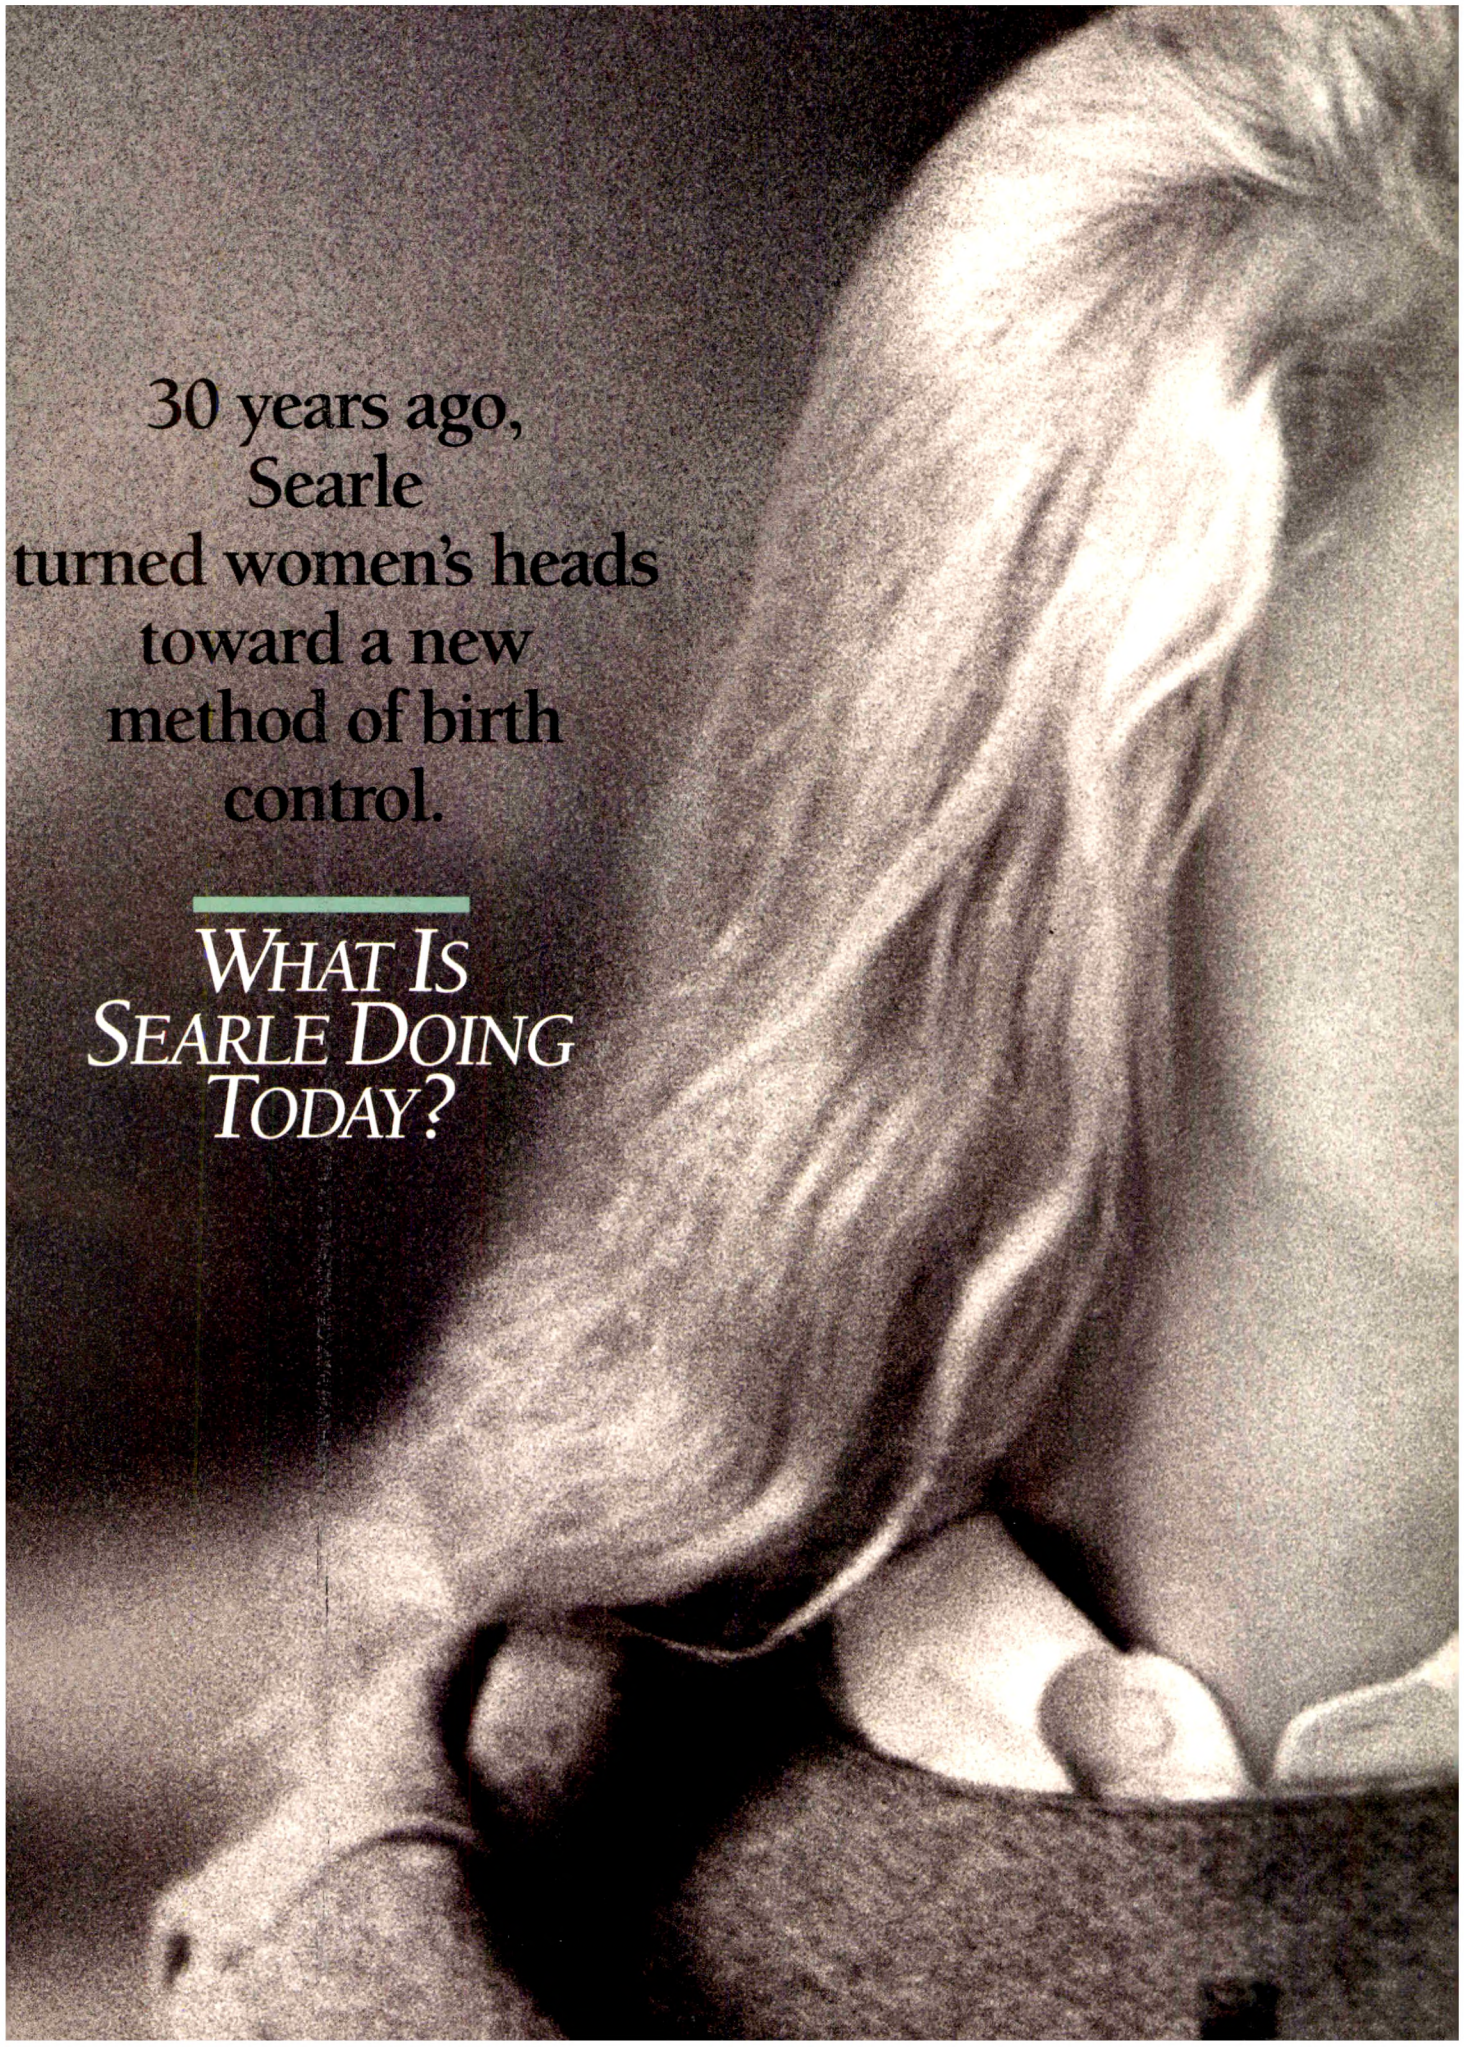
Variable 1	*Variable 2*	*r*	*p*
Maternal serum hCG	BPD/FL	−0.04	0.37
Maternal serum AFP	BPD/FL	0.06	0.16
Maternal serum hCG	Age	0.05	0.22
Maternal serum AFP	Age	0.03	0.45
Maternal serum hCG	Maternal serum AFP	0.10	0.02

BPD/FL, Fetal biparietal diameter/femur length ratio; *Age,* maternal age; *r,* Spearman Rank correlation coefficient; *p,* probability.

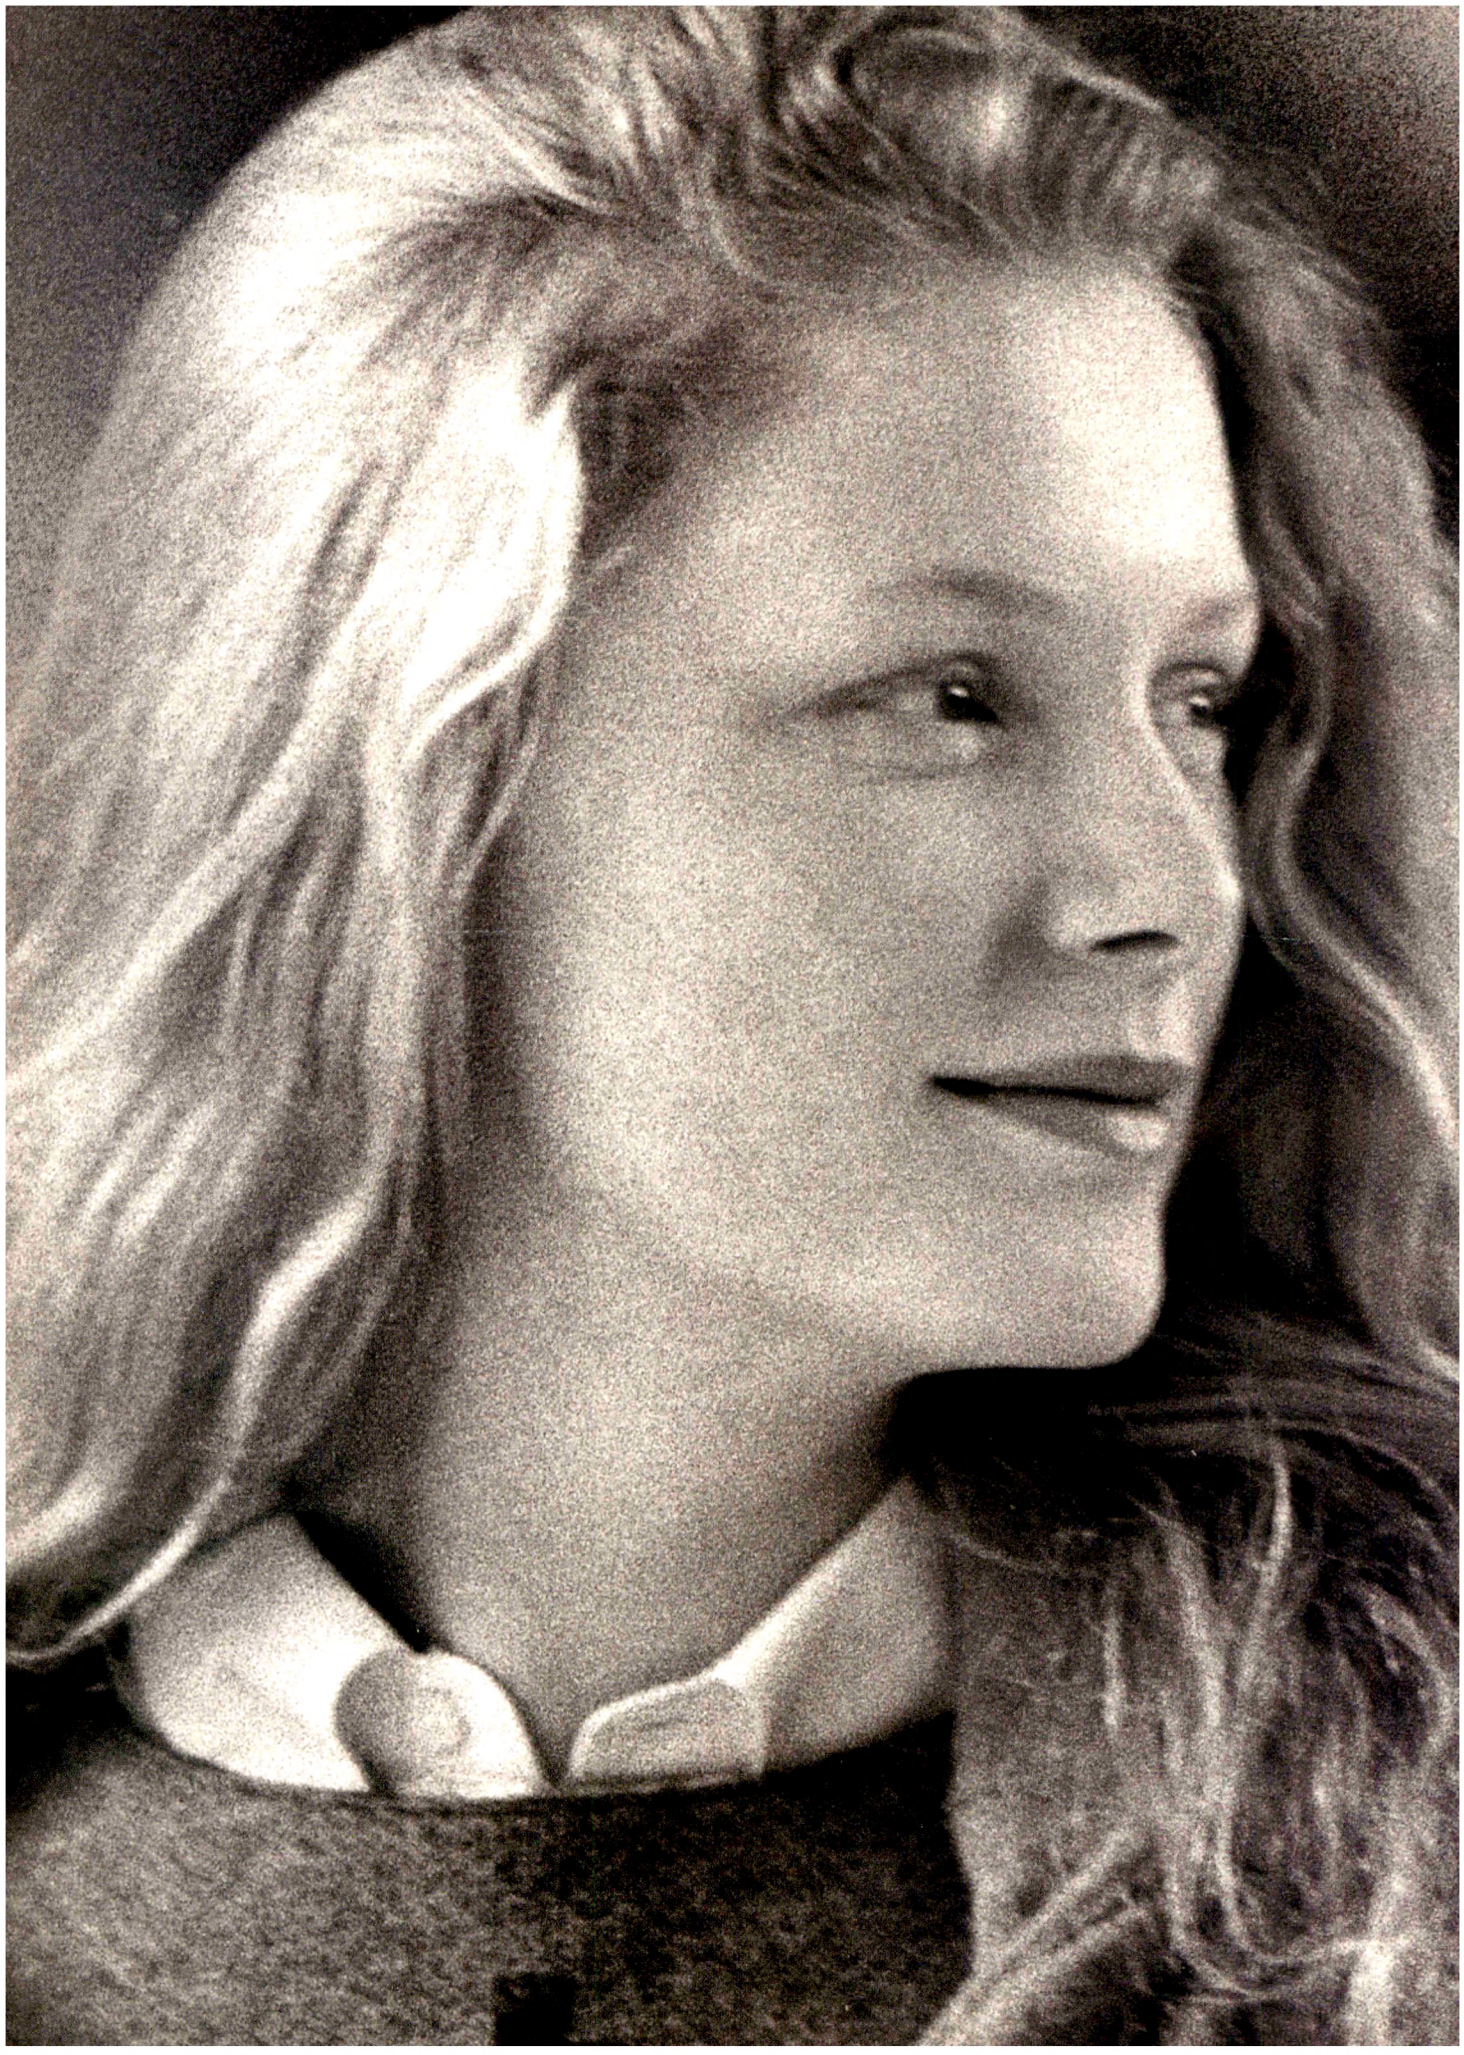
Comment

The traditional method of patient selection for Down syndrome testing by amniocentesis has been maternal age. Unfortunately, with use of this criterion alone only 20% to 30% of women with a fetus with Down syndrome are offered amniocentesis.[5] After the initial report that women carrying fetuses with Down syndrome had lower than average maternal serum AFP values,[1] this observation was confirmed and tables allowing the use of combined maternal age and maternal serum AFP concentration to estimate the risk of Down syndrome were published.[5] Several recent reports[6, 7] have confirmed the value of combining maternal age with maternal serum AFP values to select a population of women younger than the traditional cutoff age with a risk similar to that of older women. Unfortunately, even with the adjunctive, use of maternal serum AFP detection of a significantly increased proportion of fetuses with Down syndrome requires a high false-positive rate.[8]

The potential of using a combination of noninvasive measures to increase the sensitivity or decrease the false positivity of Down syndrome screening is of great cur-



rent interest. Of the possible candidates for such a role, the biparietal diameter/femur length ratio and maternal serum hCG appear to be the most promising. Inclusion of the biparietal diameter/femur length ratio is unlikely to result in a significant increase in cost, because most programs require ultrasonographic confirmation of dating before final recommendation for amniocentesis. Unlike maternal serum AFP, which is measured primarily to screen for open neural tube defects, determination of maternal serum hGC would increase screening costs. Currently, however, it appears to be the most likely candidate as a second screen since it performs more efficiently than measurement of unconjugated estriol at similar cost.



In this study we demonstrated that, after adjustment for gestational age and maternal weight, maternal serum AFP, maternal serum hCG, and biparietal diameter/femur length ratio are sufficiently independent from each other and from maternal age that they may be combined in a bayesian estimate of relative and final risk. The correlation between maternal serum AFP and maternal serum hCG found in our sample before adjustment for maternal weight (0.15) is similar to the value (0.14) reported by Wald et al.[9] in samples for which maternal weight was not available. However, maternal weight was only partially responsible for the correlation and it is probable that there is an underlying biologic association. In contrast, the lack of association between biparietal diameter/femur length ratio and either of the biochemical measures assures that the combination of retarded femur growth, increased production of hCG, and deficient production of AFP seen in Down syndrome does not occur in chromosomally normal fetuses.

Although these results are encouraging, care is required before the widespread introduction of maternal serum hCG and biparietal diameter/femur length ratio for Down syndrome screening. First, estimation of relative risk on the basis of the distributions of normal and Down syndrome pregnancies is relatively straightforward, but there is some concern that the distribution of maternal serum AFP values in pregnancies associated with Down syndrome may be dependent on maternal age or on geographic site.[10] The distribution of maternal serum hCG in pregnancies associated with Down syndrome has only been determined in a small number of cases, and similar concerns must be considered. Second, the values for the biparietal diameter/femur length ratios noted in this study are similar to those reported from Boston, but they differ from those generated in New Haven[11] with intermediate results reported from Pittsburgh.[12] Although it is possible that these differences are based on population, it is more likely that they are related to technique.[2] Unlike maternal serum AFP or maternal serum hCG determinations, over which laboratories can exert quality control, most centers rely on ultrasonographic values generated by the referring physician. Significant variations in ultrasonographic technique among participating physicians may obscure the value of biparietal diameter/femur length ratio on screening. Finally, the cost effectiveness and goals of the screening program must be evaluated. Should maternal serum hCG be determined for all subjects or only those found at increased risk by evaluation of maternal age and maternal serum AFP? We have shown that the combination of maternal age, maternal serum AFP, maternal serum hCG, and biparietal diameter/femur length ratio in the prediction of Down syndrome risk may be feasible. The proper implementation of such a program requires further study.

method of birth
control.
WHAT IS
SEARLE DOING
TODAY?

MAKING A GREAT CASE FOR DEMULEN® 1/35

- New cosmetic case design—opens with the lightest touch
- Familiar interior display—no period of adjustment for current users
- Slim and lightweight—slips into pocket, purse, or wallet
- Helps her to remember—shows, at a glance, the last day a tablet was taken

THE CASE FOR PRESCRIBING DEMULEN 1/35

- Low-dose formulation
- Minimal lipid impact
- Low incidence of some common androgenic side effects, such as acne, oily skin, and hirsutism
- Unique progestogen: ethynodiol diacetate
- No generic substitute available
- Covered by the Patient Promise® program

  If you prescribe Demulen 1/35, or any other Searle product, and do not achieve the desired therapeutic benefits, at any time, Searle will refund 100% of your patient's out-of-pocket cost for her most recent prescription for that product, *a full refund directly to your patient.*

DEMULEN® 1/35

(ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg)

Also available in the new Compack®
DEMULEN® 1/50 (ethynodiol diacetate 1 mg, ethinyl estradiol 50 mcg)

Please see adjoining page for a brief summary of prescribing information.

The physician should become familiar with the prescribing information (labeling) for this product, which discusses reported risks, such as thromboembolic disorders (including strokes and heart attacks), risk of estrogen dose, and hepatic lesions, as well as the need to monitor patients for early symptoms of any diseases or medical conditions, so use can be discontinued when appropriate. A brief summary of the prescribing information accompanies this advertisement.

DEMULEN® 1/35

(ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg)

BRIEF SUMMARY

Demulen® 1/35: Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 35 mcg. Each blue tablet in Demulen 1/35-28 is a placebo containing inert ingredients. **Demulen® 1/50:** Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 50 mcg. Each pink tablet in Demulen 1/50-28 is a placebo containing inert ingredients.

Indication and usage: For prevention of pregnancy. Pregnancy rate for products with ≥35 mcg ethinyl estradiol or ≥50 mcg mestranol is ≤1/100 woman-years. With ≤35 mcg ethinyl estradiol, rate is slightly higher; with progestogen-only oral contraceptives (OCs), rate is about 3. Precise comparisons cannot be made. Rates for other methods have been published. *Dose-related Thromboembolic Risk:* Studies showed positive association between OC estrogen dose and thromboembolic risk. It is in keeping with good therapeutics to minimize estrogen exposure. Prescribe product containing least amount of estrogen compatible with acceptable pregnancy rate and patient acceptance. Start new users on ≤50 mcg estrogen.

Contraindications: Thrombophlebitis, thromboembolic disorders, past history of deep vein thrombophlebitis or thromboembolic disorders; cerebrovascular disease, myocardial infarction or coronary artery disease, or past history of these; known or suspected breast carcinoma, estrogen-dependent neoplasia, or pregnancy; undiagnosed abnormal genital bleeding; past or present, benign or malignant liver tumors developing during use of estrogenic products.

Warnings:

Cigarette-smoking increases risk of serious cardiovascular side effects from OC use. Risk increases with age and heavy smoking (15 or more cigarettes/day) and is quite marked in women over 35. OC users should be strongly advised not to smoke. OCs are associated with increased risk of several serious conditions including venous and arterial thromboembolism, thrombotic and hemorrhagic stroke, myocardial infarction, visual disorders, hepatic tumors, gallbladder disease, hypertension, fetal abnormalities. Practitioners should be familiar with the available information relating to these and other risks.

1. *Thromboembolic disorders and other vascular problems:* Increased risk of thromboembolic and thrombotic disease associated with OCs is well established. A British study showed increased risk for fatal venous thromboembolism (TE). British and U.S. studies showed increased risk for nonfatal disease. U.S. studies showed increased risk for stroke. OC users were 2-11 times more likely to manifest these diseases without evident cause. In a study of idiopathic deep vein thrombosis and pulmonary embolism (PE), projected hospitalization rates for ages 16-40 were 47/year/100,000 users and 5 for nonusers. Overall excess mortality from PE or stroke was 1.3-3.4 deaths/year/100,000 users and increased with age. *Cerebrovascular Disorders:* In a study of stroke with and without predispositions, risk of hemorrhagic stroke was 2 times greater and thrombotic stroke 4.0-9.5 times greater in users. Mortality trends in 21 countries indicate that changes in cardiovascular mortality were associated with changes in OC prevalence. The Royal College of GPs (RCGP) reported on its prospective study: "A statistically significant higher rate of reporting of cerebrovascular accidents in Takers is evident, but the numbers are too small to justify an estimation of the degree of risk." A 1981 analysis showed a 4-fold increased mortality in users from circulatory diseases, mainly myocardial infarction (MI) and hemorrhagic stroke. Excess mortality was associated with age and smoking. A 1983 analysis showed elevated cerebrovascular disease, increasing with use to 8 yrs, including cerebral thrombosis or embolism and TIA. Peripheral arterial disease and MI were increased. Women over 30 had more arterial disease, being greatest in smokers. Arterial case-fatality was 2-3 times greater for users who smoked. Family Planning Assoc. (FPA) found significant association between OC use and stroke; increased risk for venous thrombosis and PE was 4-fold and statistically significant. Mortality from nonrheumatic heart disease was greater in ever-users. In the Walnut Creek Study, subarachnoid hemorrhage risk was associated with smoking, age, and OC use. *Myocardial Infarction:* Increased risk of MI associated with OCs was reported in Britain, as previously suspected. The morbidity study found the greater the number of risk factors for coronary artery disease (smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk, regardless of OC use. OCs were an additional risk factor. Excess rate of fatal MI was 3.5/year/100,000 users aged 30-39 and 20 for ages 40-44. (These are based on British statistics with acute MI death rates 2-3 times less than the U.S. Similar estimates for the U.S. are 25.7 for users aged 30-39 with predispositions vs 1.5 without; for ages 40-44, 86.2 vs 5.1.) Excess hospitalization rate for nonfatal MI in Britain was 3.5/year/100,000 users aged 30-39 and 47 for ages 40-44. Smoking is a major predisposing condition to MI. In terms of relative risk, nonsmoking OC users are twice as likely to have fatal MI as nonsmoking nonusers. Smoking users have a 5-fold greater risk than nonsmoking users, but a 10-12-fold greater risk than nonsmoking nonusers. Amount of smoking is an important factor. In determining importance of these risks, give serious consideration to rates in table below. Importance of other predispositions cited above in determining relative and absolute risks has not been quantified; it is likely the same synergism exists, but perhaps to a lesser extent. U.S. studies similarly relate MI, OCs, smoking, and age.

Estimated Mortality Rate from Myocardial Infarction per 100,000 Women/Year

	Aged 30-39:	*Users*	*Nonusers*	*Aged 40-44:*	*Users*	*Nonusers*
All smokers		10.2	2.6		62.0	15.9
≥15 cigarettes daily		13.0	5.1		78.7	31.3
<15 cigarettes daily		4.7	0.9		28.6	5.7
Nonsmokers		1.8	1.2		10.7	7.4
Smokers and nonsmokers		5.4	1.9		32.8	11.7

Risk of Dose: Reports of TE after use of OCs with ≥50 mcg estrogen received by drug safety committees in Britain, Sweden, and Denmark were compared with distribution expected from market research sales estimates. A positive correlation was found between estrogen dose and reporting of TE, including coronary thrombosis, in excess of that predicted by sales. OCs with ≥100 mcg estrogen were associated with higher TE risk than those with 50-80 mcg. Estrogen quantity may not be the sole factor; influence of progestogens was not considered, which may be responsible for certain discrepancies in the data. No significant differences were noted between OCs containing same estrogen dose nor between ethinyl estradiol and mestranol. In Britain certain TE conditions were associated with progestogen or estrogen dose. In Sweden reports of TE decreased when higher estrogen doses were no longer prescribed. Studies on TE risk with progestogen-only OCs have not been done. Cases have been reported for these; they are not presumed free of risk. In a U.S. case-controlled study, relative risk of OC use 1 month before hospitalization for various types of TE was calculated. If relative estrogenic potency and possible influence of different progestogens are ignored, OCs may be divided into those with <100 mcg and those with ≥100 mcg estrogen. For all cases combined, larger doses were associated with only slightly higher risk; for idiopathic cases risk was doubled with larger doses, but confidence limits overlapped and differences were not significant. Apparently there was less increased risk for cases with predispositions. In FPA study no nonhemorrhagic strokes occurred with <50 mcg estrogen, vs 13 with higher doses. Latter group also had more venous TE. TE risk in users and nonusers increases with age. OCs have been considered an independent risk factor. Decreased HDL, which relates to increased myocardial ischemia, occurs with high progestational activity. Consider amount of both steroids in choosing OC. *Persistence of Risk* after OC discontinuation was reported for circulatory disease, nonrheumatic heart disease, and cerebrovascular disease, including subarachnoid hemorrhage, cerebral thrombosis, and TIA. *Excess Mortality from Circulatory Diseases:* A U.K. prospective study estimated annual mortality from circulatory diseases for OC users and nonusers by age, smoking, and duration of use. Excess mortality was 23/100,000 users (2 and 10 for ages 25-34, 15 and 48 for ages 35-44, 41 and 179 for ages >44, for nonsmokers and smokers, respectively). Risk was significant only for smokers over 34. Most deaths were due to subarachnoid hemorrhage or ischemic heart disease. Risk for ever-users rose with parity. One study estimated risk of death with various contraceptive methods, each estimate including risk of method (eg, TE for OCs) plus risk due to pregnancy or abortion in cases of method failure. This latter risk varies with effectiveness. It concluded mortality with all methods is low and below that of childbirth, except for OC users over 40 who smoke. Heavy smokers have double the risk of smokers, light smokers about half. Mortality with OC use in nonsmokers over 40 is higher than with any other method in that age group. Lowest mortality is with condom or diaphragm backed up by early abortion. Risk of TE and thrombotic disease with OCs increases with age after 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia, and especially cigarette smoking. Based on current data, the chart gives gross estimates of risk of death from circulatory disorders associated with OCs:

Risk is: A—very high; B—high; C—moderate; D—low.	Age:	<30	30-39	≥40
Heavy smokers (≥15/day)		C	B	A
Light smokers (<15/day)		D	C	B
Nonsmokers, no predispositions		D	C,D	C
Nonsmokers, with predispositions		C	C,B	B,A

Be alert to earliest manifestations of TE disorders (eg, thrombophlebitis, PE, cerebrovascular insufficiency, coronary artery disease, MI, retinal thrombosis, mesenteric thrombosis). Should any be suspected, discontinue OCs immediately. A 4-7-fold increased risk of postsurgery TE was reported in users; if feasible discontinue OCs at least 4 weeks before surgery or in prolonged immobilization. Before resuming OCs, weigh risks of postsurgery TE complications against contraceptive needs. RCGP reported higher incidence of superficial and deep vein thrombosis in users, the former correlated with progestogen dose. Varicose veins have little effect on development of deep vein thrombosis. **2.** *Ocular lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OCs. Discontinue if there is unexplained, gradual or sudden, partial or complete loss of vision; proptosis or diplopia; papilledema; or evidence of retinal vascular lesions. Institute diagnostic and therapeutic measures. **3.** *Carcinoma:* Long-term estrogen in certain animals increases carcinomas and/or nonmalignant neoplasms, such as those of breast, uterus, cervix, vagina, ovary, liver, pituitary. Some synthetic progestogens, none currently in OCs, increase incidence of benign and malignant mammary nodules in dogs. Estrogens increase risk of human endometrial carcinoma. In case-controlled studies, increased risk (2.2-13.9 times) associated endometrial carcinoma with prolonged estrogen for menopausal symptoms. Risk was independent of other known risk factors and depended on duration of use and dose. This is supported by increased endometrial cancer incidence since 1969 in areas with cancer-reporting systems, which may be related to expanding estrogen use. There is no evidence that natural estrogens are more or less hazardous than synthetics. Of the first 30 cases of endometrial carcinoma in OC users under 40, those without predispositions occurred nearly always with no-longer-marketed sequential OCs. No statistical association is reported suggesting increased enc cancer with combination or progestogen-only OCs. Studies show no increased breast cancer with OCs or estrogens. I greater risk was noted in OC users with benign breast disease or long-term (2-4 years) use. One study found greate breast cancer with >4 years OC use prior to first full-term pregnancy. Risk of breast cancer with menopausal estrog and further increased with duration of follow-up. OCs or estrogen were related to breast cancer in connection with c factors and in various subgroups. Decrease in benign breast tumors in OC users is well known. Some studies si increased risk of cervical dysplasia, CIN, erosion, and carcinoma in long-term users. Cervical microglandular hyperp been reported. In summary, there is no consistent evidence from human studies of increased cancer risk with OC surveillance is, however, essential. In undiagnosed persistent or recurrent abnormal vaginal bleeding, consider nonf causes and take diagnostic measures to rule out malignancy. Carefully monitor users with strong family history c cancer or with breast nodules, fibrocystic disease, recurrent cystic mastitis, abnormal mammograms, or cervical d **4.** *Hepatic adenomas, etc,* have been associated with OCs. In 1 study OC formulations with high "hormonal potenc associated with higher risk, as was age over 30. Though benign, these lesions may rupture and cause fatal hemope in short- or long-term users. Two studies related risk to duration of use, being much greater after ≥4 years. Long- users have an estimated adenoma incidence of 3-4/year/100,000. Consider such lesions in users with abdomi tenderness, mass, or shock. About 25% present with abdominal masses, up to half with acute hemoperitoneum. R and lab studies may not be helpful; liver scans may show local defect. Hepatic arteriography or CAT may b Hepatocellular carcinoma risk is increased 7-20 times in users for 8 or more years. Bile duct cancer may occur with **5.** *Use in or immediately preceding pregnancy, birth defects, malignancy in offspring:* Estrogens or progestogens dur pregnancy may seriously damage offspring. Females exposed in utero to DES and other nonsteroidal estrogens m increased risk of vaginal or cervical cancer. Though OCs may not enhance this risk, monitor such patients carefully. F 90% of DES-exposed women develop benign vaginal or cervical adenosis, which could be premalignant. DES- daughters have more unfavorable pregnancy outcomes. Males so exposed may develop urogenital and sperm defec estrogens may mimic DES. Reports relate fetal exposure to female sex hormones and congenital anomalies, eg, VAC vertebral, anal, cardiac, tracheoesophageal, renal, and limb defects. There appears preferential expression by male was a 4.7-fold increased risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal wi pregnancy tests, or treatment for threatened abortion). Some exposures were very short, being only a few days. Cardic defects in children exposed to female hormones, including OCs, during early pregnancy occurred in 18.2/1,00 compared to 7.8 for those unexposed (P<.05). Female hormone exposure in utero was associated with testicular anc cancer. More twinning was reported in conceptions shortly after OC discontinuance. Female sex hormones were threatened or habitual abortion, but there is considerable evidence estrogens are ineffective and no evidence prog are effective. Triploidy and possibly other polyploidy may be increased in abortuses from women becoming pregn post-OC. These almost always abort spontaneously. It is unknown if spontaneous abortion is increased soon after OCs. Increased chromosome aberrations have been reported. Safety of OCs in pregnancy has not been demonstra out pregnancy in using OCs and always consider it if withdrawal bleeding does not occur. If 2 consecutive periods ar rule out pregnancy before continuing. If user deviates from regimen, consider pregnancy at first missed period and OCs. If pregnancy is confirmed, stop OC and apprise patient of potential fetal risks and discuss continuation of pr Users discontinuing for pregnancy should use alternative contraception for 3 months before attempting to conceive this is not based on precise information. Do not use progestogen-only or progestogen-estrogen drugs as pregnan **6.** *Gallbladder disease* risk, surgically confirmed, appeared after 2 years' use and doubled after 4-5 years in 1 appeared in 6-12 months' use in another. Bile duct cancer has been reported. **7.** *Carbohydrate and lipid metabolism:* D glucose tolerance occurs in a significant number of users; carefully observe diabetic and prediabetic patients. Trigl total phospholipids, and lipoproteins may increase. **8.** *Elevated blood pressure* (BP) occurs in some users in a few and degree may relate to progestogen dose. Hypertension prevalence in users is not higher in the first year, but i with longer exposure; in the 5th year it is 2½–3 times the first year. Age is strongly correlated with hypertension Those with history of elevated BP (hypertension), preexisting renal disease, history of toxemia or elevated BP in pr familial tendency to hypertension or its consequences, or history of excessive weight gain or fluid retention during m cycles may be more likely to develop elevated BP on OCs and should be monitored closely. Even though elevated BP in "normal" range, do not ignore implications. Follow closely, particularly those with other risk factors for cardic disease or stroke. High BP may or may not persist after stopping OCs. **9.** *Headache:* Onset or exacerbation of mig development of headache of a new pattern that is recurrent, persistent, or severe requires stopping OCs and evaluatin **10.** *Bleeding irregularities:* Breakthrough bleeding (BTB), spotting, and amenorrhea are frequent reasons for disconti BTB, as in all cases of irregular bleeding, consider nonfunctional causes. In undiagnosed persistent or recurrent bleec out pregnancy or malignancy. If pathology is excluded, time or change to another product may suffice. Change to i estrogen OC only when necessary as this may increase thromboembolic risk. Those with history of oligomenc secondary amenorrhea or without established regular cycles may be anovulatory or amenorrheic after discontinuin with such problems should be so informed and other methods encouraged. Post-use anovulation, possibly prolong occur in women without previous irregularities. Higher incidence of galactorrhea and of pituitary tumors has been as with postpill amenorrhea. One study reported 16-fold increased prevalence of pituitary prolactin-secreting tumors in with postpill amenorrhea when galactorrhea was present. **11.** *Ectopics:* In failures with combination OCs, the ratio o to intrauterine pregnancies is no higher than in nonusers. **12.** *Breast feeding:* OCs may decrease quantity and quality A small fraction of OC steroids appears in milk. Effects if any on child are unknown. If feasible defer OCs until after **13.** *Infertility* may occur after discontinuing OCs. While impairment diminishes with time, there is still an appreciable d in nulliparas aged 25-29 after 30 months; difference is negligible after 48 months. In nullips aged 30-34 impairment to 72 months and is more severe for 2-year users. In paras aged 25-34, difference is negligible after 30 months. **Prec** Conduct complete history and physical prior to OC use and annually thereafter. Include breasts, abdomen, and pel BP, Pap, and lab tests. Preexisting uterine leiomyomata may enlarge. Mental depression may occur; with positive observe carefully and discontinue if serious recurrence. Fluid retention may occur; prescribe cautiously and monitor in convulsive disorders, migraine, asthma, or cardiac, hepatic, or renal dysfunction. History of jaundice in pregnancy i risk of recurrence on OCs; observe carefully and discontinue if it occurs. Cholestatic jaundice occurred after troleandomycin use. OC/cyclosporine combination may be hepatotoxic. Steroids may be poorly metabolized in liver dy and should be given cautiously. Tryptophan metabolism may be disturbed and result in pyridoxine deficiency; mega anemia has been reported. Serum folate may be depressed and may be exacerbated in post-OC pregnancy. Advise pa of OC use when submitting specimens. Endocrine and liver function tests may be altered; repeat abnormal tests after for 2 months. These have been observed: increased BSP retention and other abnormalities in liver function tests; i prothrombin and coagulation factors VII, VIII, IX, X; decreased antithrombin III, increased platelet aggregability; i thyroid-binding globulin leading to increased circulating total thyroid hormone (PBI, T^4); decreased T^3 uptake, unalte T^4, decreased pregnanediol excretion; reduced metyrapone response; increased blood transcortin, corticosteroid, trig phospholipid; reduced serum folate; impaired glucose tolerance; altered plasma trace minerals. Influence of prolonge on pituitary, ovarian, adrenal, hepatic, or uterine function, or on immune response not established. OCs may mask climacteric. Cervical chlamydial and gonorrheal prevalence is increased; do not assume OC protects against chlamy HIV seropositivity was associated with OC use. *Information for patients.* See patient labeling. *Drug interactions.* OC effec may be decreased and more BTB occur with rifampin, isoniazid, ampicillin, neomycin, penicillin V, tetracycline, chloram sulfonamides, nitrofurantoin, griseofulvin, barbiturates, phenytoin, carbamazepine, primidone, phenylbutazone, an tranquilizers, antimigraines. OCs may alter effectiveness of oral anticoagulants, anticonvulsants, tranquilizers, antidepressants, antihypertensives, theophylline, caffeine, vitamins, hypoglycemics, clofibrate, glucocorticoids, acetam **Adverse reactions:** Increased risk of the following serious adverse reactions has been associated with OCs: thrombo and thrombosis; pulmonary embolism; arterial thromboembolism; Raynaud's disease, myocardial infarction; thrombosis; cerebral thrombosis; cerebral hemorrhage; hypertension; gallbladder disease; Budd-Chiari syndrome adenomas and other hepatic lesions, with or without intra-abdominal bleeding, liver cancer, congenital abnormalities. evidence of association between the following and OCs, though confirmatory studies have not been done: m thrombosis; neuro-ocular lesions, eg, retinal thrombosis and optic neuritis. The following are believed drug related: vomiting, gastrointestinal symptoms, BTB, spotting, change in menstrual flow, dysmenorrhea, amenorrhea during a use, infertility post-OC, edema, chloasma or melasma, which may persist post-OC, breast changes (tenderness, enla secretion), weight changes, change in cervical erosion and secretion, endocervical hyperplasia, lactation decrease, ch jaundice, migraine, enlarged uterine leiomyomata, allergic rash, mental depression, reduced carbohydrate tolerance candidiasis, change in corneal curvature (steepening), intolerance to contact lenses. Association not confirmed or ref premenstrual-like syndrome, cataracts, libido changes, chorea, appetite changes, cystitis-like syndrome, headache, par nervousness, dizziness, auditory disturbances, rhinitis, fatigue, backache, hirsutism, scalp hair loss, erythema multi nodosum, hemorrhagic eruption, herpes gestationis, hidradenitis suppurativa, hemolytic uremia, malignant hype impaired renal function, acute renal failure, sometimes irreversible, itching, vaginitis, porphyria, PVCs, abnorm pulmonary hypertension, TTP, anemia, pancreatitis, hepatitis, colitis, Crohn's disease, gingivitis, dry socket, lupus erythe rheumatoid arthritis, pituitary tumors (eg, adenoma) with amenorrhea and/or galactorrhea after use, malignant m endometrial, cervical, breast, and bile duct carcinoma. **Acute overdosage:** Serious ill effects have not been repor large acute doses of OCs in young children. Nausea and withdrawal bleeding might occur. **Important note: C prescribing information should be consulted prior to use and is available on request.**

The course of labor after endurance exercise during pregnancy

James F. Clapp III, MD
Burlington, Vermont

This study was designed to test the hypothesis that continuation of a regular running or aerobics program, or both, during the latter half of pregnancy would have a negative effect on the course and outcome of labor. The onset, course, and outcome of labor were independently monitored in 131 well-conditioned recreational athletes who had an uneventful first half of pregnancy. Daily exercise performance was quantitated before conception and throughout pregnancy. Comparisons were made between the 87 women who continued to exercise regularly at or above 50% of their preconceptional level throughout pregnancy and the 44 who discontinued their regular exercise regimen before the end of the first trimester. The incidence of preterm labor was similar in the two groups (9%). Labor began significantly earlier in the exercise group (277 ± 6 vs 282 ± 6 days). The women who continued to exercise had a lower incidence of abdominal (6% vs 30%) and vaginal (6% vs 20%) operative delivery, and active labor was shorter (264 ± 149 vs 382 ± 275 min) in those who were delivered vaginally. Finally, clinical evidence of acute fetal stress (meconium, fetal heart pattern, and Apgar score) was less frequent in the exercise group (50% vs 26%), although birth weight was reduced (3369 ± 318 vs 3776 ± 401 gm). These data negate the initial hypothesis and indicate that, in well-conditioned women who regularly perform aerobics or run, continuation of these exercise regimens has a beneficial effect on the course and outcome of labor. (AM J OBSTET GYNECOL 1990;163:1799-805.)

Key words: Exercise, pregnancy, labor

It is likely that regular physical activity, as well as the improved physical fitness that accompanies it, has a beneficial effect on the course and outcome of labor. However, a direct assessment of this relationship is difficult because of the confounding effects of the multiple exercise variables involved and the other maternal, uterine, fetal, and obstetric factors that are known to influence labor. Thus it is not surprising that the reports dealing with the impact of exercise during pregnancy on labor have been divergent with some reporting benefit[1,2] and others either no effect[3-6] or a detrimental one.[7,8]

The purpose of this study was to provide a definitive answer to the question, does continuation of a regular exercise regimen throughout pregnancy influence the course and outcome of labor? In an attempt to control the multiple variables involved, the current study used a prospective design and was limited to well-conditioned recreational athletes who performed one of two forms of high-intensity exercise (running or aerobics) in which a large fraction of the body's muscle mass is used against gravity for relatively prolonged periods of time. The experimental design also included a relatively large sample size, a matched populace of recreational athletes who discontinued exercise, daily monitoring of exercise performance before and during pregnancy, and on-site, independent monitoring of the course and outcome of labor. The hypothesis tested was that when a regular running or aerobics regimen is continued at or above 50% of preconceptional levels throughout pregnancy it has a negative impact on the course and outcome of labor. The objective outcome parameters included indices of labor onset, management, course, complications, outcome, and fetal stress.

From the Department of Obstetrics and Gynecology, The University of Vermont College of Medicine.

Material and methods

Between July 1983 and February 1990, we prospectively monitored the spontaneous exercise performance of 67 recreational runners and 64 aerobic dancers who, with the exception of preterm labor, had clinically normal pregnancies, with labor and delivery under surveillance by study personnel. All subjects had been exercising regularly for at least 6 months before conception, three or more times each week for at least 30 minutes each session at an intensity >50% of their individual maximum capacity. Written informed consent was obtained from each subject at the time of enrollment. Because of very real human subject concerns and an unwillingness on the part of many subjects to change their specific exercise regimen, the subjects were not randomized prospectively to different regimens. Rather, they were divided into two groups on the basis of their spontaneous level of exercise perfor-

mance during pregnancy. The 46 runners and 41 aerobic dancers who continued to exercise at or above 50% of their preconceptional performance level throughout the 10 lunar months of pregnancy formed the continued exercise group. The 21 runners and 23 aerobic dancers who spontaneously stopped their regular exercise regimen by the end of the first trimester formed the discontinued exercise or reference group.

To quantitate each individual's exercise, we measured maximum oxygen consumption before conception and the relationship between heart rate and oxygen consumption during graded exercise in the laboratory before conception and every 6 to 8 weeks during pregnancy. Concurrent field heart rate data and the time spent in exercise were gathered with a portable telemetry system, and the data were used to calculate overall weekly exercise performance. This was quantitated by means of the training effect method and was expressed as a duration-intensity index (product of weekly duration and average weekly intensity).[9]

Pregnancy was confirmed within a few days of missed menses (β-human chorionic gonadotropin level) and dates were confirmed by early ultrasonography 53 to 60 days after the last menstrual period. With the exception of preterm labor, the pregnancies were all clinically normal and the course and outcome of each labor were monitored by an independent observer who was present but was not involved in the subject's clinical care.

The onset of labor was defined as the onset of regular uterine contractions followed by progressive cervical change. Preterm labor was defined as the onset of labor before 263 days' gestation (<37½ weeks of gestation completed), and premature rupture of the membranes was defined as the onset of persistent vaginal fluid leakage before the onset of subjective uterine activity that was confirmed on examination by an alkaline pH and ferning of the fluid. The start of the active phase of labor was set at 4 cm of cervical dilation with regular uterine contractions, and women who were further advanced in labor at the time of initial evaluation were not included in the study. An abnormal fetal heart pattern was defined as one that initiated medical intervention and the Apgar score was assigned by the delivery room nurse or pediatrician in attendance.

Significant between-group differences for normally distributed parameters were detected with the unpaired Student t test. Differences in exercise performance were assessed with the Wilcoxon–Mann-Whitney test. Between- and within-group differences in incidence were detected by means of the χ^2 statistic with the Yates correction for small groups. Regression analysis was used to detect any within-group effect of weight gain, exercise performance, preconceptional weight, and parity on numeric parameters. Significance was set at the 0.05 level.

Results

Maternal characteristics. The subjects were all white, were middle or upper socioeconomic class, and worked part-time or full-time. None smoked, alcohol intake was limited (maximum recorded was four glasses of beer per week), and all subjects ate an adequate caloric, well-balanced diet that was low in simple sugar and high in complex carbohydrate. They were all in excellent health and averaged 31 years of age (range 24 to 38). Preconceptional weight and height ranged between 42.3 and 78.4 kg and between 155 and 185 cm, respectively. Most (128/131) had a normal menstrual pattern; 52% of the populace were nulliparous and 47% were primiparous. Two subjects were secundiparous. The only obstetric risk factors included one subject with a history of diethylstilbestrol exposure, two with a history of bulimia in college, and one with a prior preterm delivery. Data on family obstetric history were not obtained, but there were no between-group differences in the distribution of birth orders, birth weights, or route of delivery of the subjects themselves.

All subjects were fit as assessed by preconceptional morning pulse rate (range 48 to 62 beats/min), maximal oxygen consumption (range 43 to 68 ml/kg/min), weight for height (range of ponderal index 1.06 to 1.38), and percent body fat (range 10% to 24%). When referenced to current normative standards,[10] all subjects had maximum oxygen consumptions in the upper 15% of the overall populace with an average of 54.3 ml/kg/min.

There were no significance between-group differences in any of these demographic, morphometric, lifestyle, and obstetric variables or in the four objective indices of fitness. In fact, the only two discernible between-group differences were that the women who discontinued their regular exercise regimen in early pregnancy had an overall level of exercise performance before conception that averaged 25% less than that of the women who continued their regular regimen throughout pregnancy (Table I) and their average pregnancy weight gain (17.2 kg) was 3.6 kg greater than that of those who continued exercise (13.6 kg).

Maternal exercise performance. Before conception running performance ranged between 14 and 68 km each week at a pace between 3.9 and 6.1 min/km and an intensity ranging between 51% and 83% of maximum. Participation in aerobics ranged between 3 and 11 sessions each week at an intensity between 54% and 90% of maximum during the 25- to 30-minute high-intensity phase of the workout. The mean group pulse rate was 166 beats/min during both aerobics and running, but there was a great deal of individual variation with individual average exercise pulse rates ranging between 122 and 190 beats/min. The relationship between pulse rate and exercise intensity was extremely variable such that a pulse rate of 140 beats/min for

Table I. Maternal exercise performance

	Control (N = 44)	*Exercise (N = 87)*	*Significance*
Duration-intensity index before pregnancy	9840 ± 303	13,070 ± 332	0.01
During pregnancy* (%)	14 ± 17	68 ± 16	0.01
Last half of pregnancy* (%)	5 ± 10	65 ± 17	0.01
9-10 mo of pregnancy* (%)	2 ± 3	60 ± 18	0.01

Values are mean ± SD.
*Percent of prepregnancy value.

different individuals represented an oxygen consumption that ranged between 42% and 73% of measured maximum capacity.

During the first half of pregnancy the intensity of exercise was maintained at or near preconceptional levels (51% to 90% of maximum) in the continued exercise group. However there was an average decrease in running distance and number of aerobics classes to 29 km/wk and 4.8 classes per week, resulting in a 23% average reduction in the time spent in exercise during the first half of pregnancy. The relationship between exercise intensity and pulse rate became more variable. At 8 and 16 weeks a pulse rate of 140 beats/min for different individuals represented an oxygen consumption that ranged between 31% and 76% of preconceptional maximum capacity. During the latter half of pregnancy the range of intensity decreased to 50% to 76% of maximum capacity, but the range of the time spent in exercise increased (40% to 160% of preconceptional duration). As a result the average running distance and overall aerobics effort remained stable. Again there was wide individual variation in both pulse rate and its relationship to exercise intensity. Individual average pulse rates during exercise ranged between 110 and 187 beats/min, and a rate of 140 beats/min for different individuals represented an oxygen consumption that ranged between 35% and 68% of preconceptional measured maximum capacity. Thus during pregnancy the slope of the relationship between individual pulse rate and exercise intensity, measured as a percentage of preconceptional maximum absolute oxygen consumption, changed in different directions at different time points in pregnancy, and individual average pulse rates, which ranged between 110 and 195 during exercise in pregnancy, were not by themselves an accurate index of individual exercise intensity. The individual range of overall exercise performance for the entire pregnancy ranged between 50% and 109% of preconceptional levels. For the latter half of pregnancy the range in individual overall performance was 50% to 122% of preconceptional levels. Mean values for the entire group are listed in Table I for the entire pregnancy, the last 5 months, and last 2 months.

Although the women who discontinued regular exercise had an overall preconceptional performance level that averaged 25% less than that of those who continued, their overall level of performance still represented an average of 26 km/week for the runners and an average of four or five classes per week for those who performed aerobics at similar intensities. The majority of these women (n = 37) spontaneously discontinued exercise in early pregnancy for one of two reasons. First, dealing with the extreme fatigue and nausea of early pregnancy completely abolished their desire to exercise early on, and they simply never prioritized the time to begin their regular exercise regimen again during pregnancy. Second, they could not cope emotionally with the reduction in performance level suggested by their physicians or their own uncertainties concerning the potential impact of the exercise on the pregnancy, which were reinforced at the initial prenatal visit. As a result they simply stopped until after delivery. In the remainder minor injury, job pressures, or paternal concerns played a major role. As a group (Table I) their average level of overall performance fell to 2% to 5% of preconceptional levels by the end of the fifth lunar month.

Onset of labor. As detailed in Table II, continuing the ballistic motion associated with running and aerobics throughout pregnancy did not increase the incidence of either the onset of labor before 37½ weeks of gestation were completed or membrane rupture before the onset of perceived labor. The incidence of spontaneous membrane rupture that eventually necessitated induction of labor was also similar in the two groups. However, the onset of labor at or near term occurred 5 days earlier on average in the women who continued exercise. When examined individually within groups, prepregnancy weight, pregnancy weight gain, parity, preconceptional or pregnant level of exercise performance, and exercise type (aerobics or running) did not have a significant effect on gestational length (all individual R^2 values <0.02).

Obstetric management. As a group the women who continued their regular exercise regimens throughout pregnancy experienced significantly less obstetric intervention (Tables III and IV). This included highly significant reductions in both elective and indicated labor stimulation, episiotomy, and use of epidural anesthetic, as well as both vaginal and abdominal opera-

Table II. Onset of labor

tive delivery. This was not due to a between-group difference in the number of parous subjects. Rather, it was directly related to a significant increase in the incidence of both protraction disorders and second-stage arrest in the discontinued exercise group, which created a greater need for stimulation and operative intervention. The latter also had a causal role in the increased duration of active labor in the control group. However, when the cases in which cesarean section was the method of delivery were excluded, active labor was still 30% shorter on average in the exercise group, and within both groups parous subjects had significantly shorter labors than nulliparous women. Within the discontinued exercise group there was a significant direct relationship ($R^2 = 0.1103$) between maternal weight gain and the length of labor, and χ^2 analysis indicated that a weight gain in excess of 18 kg was associated with a significant increase in the incidence of both protraction disorders and operative delivery. These relationships were not present in the continued exercise group. Similarly, exercise performance before or during pregnancy and exercise type did not have any additional effect in the exercise-continued group.

Fetal condition and outcome. The parameters evaluated for assessing the fetal condition and outcome included meconium-stained fluid, fetal heart patterns, visual evidence of a nuchal cord at delivery, and Apgar score. Scalp pH was determined infrequently and was always in the normal range. A fetal heart rate pattern was thought to be abnormal only if it initiated a clinical response on the part of the midwife or physician (oxygen, maneuvers to shorten the second stage, abdominal delivery). As can be seen in Table V, each of these four indices of fetal stress occurred more frequently in the discontinued exercise group. Undoubtedly, these occurrences were also a factor in the higher rate of obstetric intervention in the discontinued exercise group. Within-group interactive effects on the four parameters used as evidence of fetal stress were not observed. Finally, birth weight was reduced by approximately 400 gm in the exercise group. This was not related to a between-group difference in the sex of the offspring (exercise continued, 52% male; exercise discontinued, 48% male). Within the discontinued exercise group a birth weight >4000 gm was associated with an increased incidence of protraction disorders and operative delivery. Within the exercise-continued group there was no detectable relationship between birth weight and obstetric intervention with birthweight cutoffs of 3500 and 3750 gm (only one infant weighed >4000 gm). Within the overall populace there was a significant relationship ($r^2 = 0.2768$) between birth weight and pregnancy weight gain. As discussed elsewhere,[11] this correlation is due to the independent effects of exercise on both parameters.

Comment

These data negate the initial hypothesis and clearly indicate that, in physically fit women who performed aerobics or ran on a regular basis before pregnancy, continuing a regular running or aerobics exercise program above a maintenance level throughout pregnancy had a beneficial effect on multiple aspects of the course and outcome of labor. Overall, continued exercise was

associated with a shorter labor, less need for obstetric intervention, and fewer signs of fetal stress. Additional correlations suggest that the effect of continued exercise on the management and duration of labor is partially due to its effect on birth weight.[11]

Despite the fact that the 87 women who continued to exercise throughout pregnancy did so at intensities and for time periods well above currently recommended levels, there was no evidence, other than a reduction in birth weight, that the theoretical concerns about these types of exercise in late pregnancy were valid. There was no evidence to support the concern that exercise triggers preterm labor or increases the incidence of membrane rupture before the onset of labor. No cases of abruptio placentae were noted, the incidence of nonvertex presentations was not increased, and clinical evidence of fetal compromise at the onset or during labor was not found. An additional benefit of continuing a regular exercise regimen was the limitation in maternal pregnancy weight gain. However, the fact that this was largely confined to the women runners[10] indicates that it was not a significant determinant of the course and outcome of labor, which did not vary with exercise type.

Although not specifically examined, the rate of progress in and the duration of labor, coupled with the decreased incidence of protraction disorders in the exercise group, suggested that exercise at these levels in late pregnancy may have had a positive effect on cervical ripening and uterine coordinate activity without initiating preterm labor. In fact, three subjects initially qualifying for the exercise group were excluded from analysis because labor was so short that they entered the labor suite at or near full dilatation and were delivered before adequate assessment could be accomplished. These observations, coupled with the low incidence of episiotomy and operative vaginal delivery and an average 40-minute second stage, clearly do not support the concern raised in several earlier publications that these types of exercise may increase the resistance of the perineal tissues.[7,8]

As discussed elsewhere,[11] the difference in birth weight was primarily due to a reduction in fetal fat mass in the offspring of the women who continued a regular exercise regimen throughout late pregnancy. This did not create clinical difficulty in the neonatal period, and if the leanness persists, it may actually turn out to be an advantage in terms of cardiovascular risk in later life. It is conceivable that this difference in birth weight could place the preterm infant at greater risk of morbidity and mortality. However, as the birth weight difference is primarily a difference in fat and the majority of in utero fat deposition occurs after the thirty-fourth week, the difference in birth weight should be minimal in infants born to exercising women before that point in gestation.

Several shortcomings of the current study should be emphasized. First, because of human subject concerns and individual commitment to a chosen exercise regimen, exercise performance during pregnancy was sim-

ply monitored, not randomly assigned. As such, group assignment was essentially self-selected and could potentially introduce bias. However, as detailed above, the two groups were well matched for most demographic, obstetric, morphometric, and life-style factors that are known to affect birthweight and the course and outcome of labor. While this match does not control for some variables such as potential individual differences in hormonal milieu, the discontinued exercise group did provide a valid reference for most of the clinically recognized dependent variables that influence labor. In addition, although the women in the discontinued exercise group performed significantly less exercise each week before conception than those who continued to exercise throughout pregnancy, objectively they were equally fit before pregnancy and, if anything, their level of fitness decreased during pregnancy, which should have had a reverse bias effect on the course and outcome of labor.[2]

While it is possible that the lower level of overall preconceptional exercise performance in the discontinued exercise subgroup could have reflected additional factors that influenced the course and outcome of labor, we could not identify any. Although the performance of this group was relatively lower before conception, it was still significant (27 km/wk or four or five aerobic sessions per week), and they still were extremely fit (average maximum oxygen consumption of 54.2 ml/kg/min) and averaged 150 minutes of high-intensity endurance exercise each week. On the basis of these data we doubt that the difference reflected unrecognized factors that biased labor outcome and speculate that the between-group difference in preconceptional performance simply indicates that women who consistently exercise at a higher overall level are more likely to continue their exercise regimen during pregnancy than women who work at a slightly lower level. Finally, there was no consistent relationship between a subject's intended level of exercise performance during pregnancy and her actual level of performance; i.e., many of the women who planned to continue a vigorous exercise regimen stopped and many women who were hesitant about their ability to maintain an exercise regimen did so. Thus, although the design was not ideal, the reference or discontinued exercise group did not have an easily detectable selection bias of major proportion and the outcomes observed provide the data needed to ethically permit a randomized trial of exercise prescription during pregnancy.

Second, to isolate the effects of regular exercise on the course and outcome of labor, these data were obtained in a select group of well-conditioned recreational athletes who had been regularly performing one of two specific types of exercise for several years. As such, extrapolation of these findings to other women or other exercise regimens would be inappropriate and the results clearly are not applicable to the overall obstetric populace. This restriction is important and is supported by the findings of several well-controlled studies that used less demanding exercise regimens in other groups of women and noted either no or minimal impact on the course and outcome of labor.[4-8] This restriction probably is particularly relevant to the group of women who wish to begin a training regimen for the first time during either the periconceptional period or early pregnancy. Nonetheless, these findings are in accord with the general consensus in the literature that exercise does not adversely affect the course and outcome of labor,[1-6] and the selective nature of the populace studied, along with the monitoring of both the actual level of exercise performance and the course of labor, undoubtedly enhanced our ability to detect the noted differences.

Finally, it is important to emphasize that the 87 women who continued to run and perform aerobics throughout pregnancy did so at a relatively high overall level of performance and that, within this populace, pulse rate was a relatively poor predictor of exercise intensity. These women's level of exercise performance far exceeds that reported in earlier studies.[1, 2, 4-8] The fact that the hypothesized ill-effects were not observed at these relatively high levels of performance indicates that well-conditioned women probably can continue to exercise at relatively high intensities for periods of ≥30 minutes without detriment. Likewise, using a pulse rate of 140 beats/min to indicate a certain exercise intensity or level of effort in well-conditioned women during pregnancy appears imprecise.

In summary, these data, which were obtained in well-conditioned, low-risk women, indicate that, in this populace, continuing a regular exercise regimen of running or aerobics throughout pregnancy has a beneficial effect on multiple aspects of the labor process. Furthermore, despite a high overall level of performance, the anticipated complications were not observed. While several well-controlled studies suggest that these findings probably are not applicable to other types of women or exercise regimens,[1,2,4-8] they are reassuring and, in conjunction with the other published human data, suggest that current guidelines for exercise in pregnancy should be carefully evaluated to determine if the potential maternal benefits of exercise may be realized without increasing fetal and neonatal risk.

Neonatal morphometrics after endurance exercise during pregnancy

James F. Clapp III, MD, and Eleanor L. Capeless, MD
Burlington, Vermont

This study was designed to test the hypothesis that continuation of a regular running and/or aerobics program during late pregnancy at or above 50% of preconceptional levels limits fetal growth. Accordingly, detailed neonatal morphometric data were gathered in the offspring of two groups: 77 well-conditioned recreational runners and aerobic dancers who were delivered at term after continuing their exercise regimen at or above 50% of the preconceptional level throughout pregnancy and 55 matched controls. Daily exercise performance was quantitated before conception and throughout pregnancy. Significant reductions in birth weight (−310 gm), birth weight percentile (−20), ponderal index (−0.24), its percentile (−30), and the fetoplacental weight ratio (−0.7) were seen in the offspring of the exercise group whereas crown-heel length (51.4 cm) and head circumference (35.0) were similar in the two groups. Reductions in two-site skin-fold thickness (−1.5 mm), skin-fold percentile (−30), calculated percent body fat (−5.0%), and fat mass (−220 gm) in the offspring of the exercise group confirmed the asymmetric pattern of growth restriction and indicated that approximately 70% of the difference in birth weight could be explained by the difference in neonatal fat mass. In runners, the relative level of exercise performance in the last 5 months of pregnancy explained 40% of the variability in birth weight over an 1100 gm birth weight range. We conclude that continuation of a regular aerobic or running program at or above a minimal training level during late pregnancy results in an asymmetric pattern of growth restriction that primarily impacts on neonatal fat mass. (AM J OBSTET GYNECOL 1990;163:1805-11.)

Key words: Exercise, pregnancy, birth weight

The interaction between exercise performance during pregnancy and pregnancy outcome is complex but appears to be based on the interplay between the maternal physiologic adaptations to exercise and the physiologic adaptations to pregnancy.[1-3] The magnitude of the exercise-induced adaptations is determined by the type, intensity, frequency, and duration of the exercise while the magnitude of the adaptations to pregnancy is a function of the time point in the pregnancy when the exercise is carried out. Given this number of variables, it is not surprising that the reported impact of exercise during pregnancy on birth weight has varied, with investigators reporting a reduction,[1,4] no effect,[5-8] or an increase.[9,10]

In an attempt to control the multiple variables involved, the current study was limited to well-conditioned recreational athletes who performed one of two forms of high-intensity exercise (running and aerobics) in which a large fraction of the body's muscle mass is used against gravity for relatively prolonged

Data presented as mean ± SD.

periods of time. The experimental design included a carefully matched control populace, and individual exercise performance was prospectively monitored before conception and throughout pregnancy. The hypothesis tested was that when recreational running and/or aerobics are continued during late pregnancy, at or above 50% of preconceptional levels, they limit fetal growth. The objective outcome parameter was neonatal morphometry.

Material and methods

Between July 1983 and January 1990, we prospectively monitored the spontaneous daily exercise performance of 42 recreational runners and 35 aerobic dancers who exercised for at least 30 minutes, three or more times each week before conception and who were delivered at term (>266 and <294 days) after continuing their chosen form of exercise at or above 50% of the preconceptional level throughout pregnancy. These women constituted the exercise group. Exercise performance was quantitated before and during pregnancy by measuring heart rate and the duration of exercise daily during field exercise. These data, coupled with the periodic laboratory evaluation, were used to quantitate weekly and monthly exercise performance by means of the training effect method and were expressed as a duration-intensity index (product of weekly duration and average weekly intensity).[11]

We also enrolled and monitored a control group of 55 physically active, fit women who did not plan to maintain a continuous, high-intensity exercise regimen after confirmation of pregnancy (first trimester). They were matched with the exercise group for general health, physical fitness, education, family income, age, parity, contraceptive use, pregravid weight, job type, dietary intake, sleep-activity cycles, smoking, and alcohol intake. Before pregnancy these women either ran, performed aerobics, or played racquet sports on a more intermittent basis than those in the exercise group and their exercise performance was monitored in a similar fashion.

All pregnancies included in the analysis were clinically normal, each subject had between 11 and 14 antenatal visits with a private obstetrician, and all were delivered at term. An additional 33 subjects who were initially enrolled in the project before conception and who were excluded from this analysis included 22 cases of either infertility or abortion (9 control, 13 exercise), three cases of mild pregnancy-induced hypertension (two control, one exercise), and seven cases in which labor began before 266 days' gestation (four exercise, three control). Written informed consent was obtained from each subject before enrollment. Pregnancies were confirmed within a week of missed menses (by β-subunit human chorionic gonadotropin) and the dates were confirmed by ultrasonographic examination at 53 to 60 days after the last menstrual period. The relationship between exercise intensity and heart rate was determined before conception and every 6 to 8 weeks during pregnancy by measuring heart rate and oxygen consumption during either treadmill exercise or aerobics. A crude estimate of historic dietary intake (kilocalories and component mix) was obtained by questionnaire at the time of initial preconceptional evaluation. At each testing session during pregnancy, all subjects were questioned to determine if there had been a significant change in the quantity or quality of their diet.

Neonatal and placental morphometric measures were obtained within 2 hours of birth by one of two individuals. After the infant had been carefully dried, weight was determined by the nearest 10 gm with an accurately calibrated balance beam or electronic scale. The measurement of crown-heel length to the nearest millimeter was carefully standardized by use of a specially constructed measurement box and the tonic neck reflex.[12] This technique had a coefficient of variation of <1% and, on the basis of a comparison with the values charted by the nurses, resulted in a shorter (2% to 5%) length than that obtained with the routine clinical method. Circumferential measurements of the head, chest, and abdomen were obtained to the nearest millimeter with a narrow flexible tape used in the recommended fashion.[13] The coefficient of variation of each measurement was <3%. Triceps and subscapular skinfold thicknesses were measured on the right side with John Bull calipers and had coefficients of variation under 6%. Ponderal index was calculated as birth weight in grams × 100 divided by the cube of the crown-heel length in centimeters.

These morphometric data were referenced to normative values for birth weight, crown-heel length, ponderal index, circumferences, and skin-fold thicknesses established in a random sample (n = 335) of our overall term newborn populace to determine percentiles. (These normative data are being submitted separately for publication and therefore are not detailed here.) The neonatal sample was obtained over a 2½-year period by use of random grab sampling throughout. With birth weight used as the objective criterion, the sample

Table II. Additional maternal characteristics

Parameter	*Control*	*Exercise*	*Significance*
Age (yr)	30.1 ± 3.3	30.6 ± 2.5	NS
Pregravid weight (kg)	58.1 ± 5.9	57.7 ± 5.2	NS

Blood glucose (mmol/L)	4.88 ± 0.61	4.83 ± 0.70	NS

Data presented as mean ± SD. Alcohol intake is the average number of mixed drinks, glasses of wine, or cans of beer each week during pregnancy. Blood glucose was measured on whole blood at approximately 36 weeks' gestation on a random postprandial sample obtained at standing rest.

was normally distributed and statistically no different from that of all term infants born at the institution. The skin-fold percentile was used to estimate body fat, which had been determined with the original Dauncy method and formula in the reference populace.[14] Within that populace the r value between skin-fold thicknesses and calculated percent body fat was 0.95.

After gross inspection and removal of surface clot, cord, and membranes, each placenta was blotted and weighed to the nearest 5 gm. Its volume was determined to the nearest 5 ml by saline solution displacement and its chorionic surface area was measured to the nearest square centimeter by planimetry.[15]

Significant between-group differences for normally distributed parameters were detected with the unpaired Student's t test. Other parameters were assessed with the Wilcoxon–Mann-Whitney test. Single and multiple regression analysis was used to seek a dose-response relationship between exercise performance and morphometric outcome. Significance was set at the 0.05 level.

Results

Maternal characteristics. In both groups the subjects were all from the middle or upper socioeconomic class and worked part-time or full-time. All ate a well-balanced, high-complex-carbohydrate diet with adequate calories and had similar rest-activity patterns before conception. As shown in Table I, before conception all women in both groups were fit as assessed by morning pulse rate, maximal oxygen consumption, and percent body fat. There were no significant between-group differences in these parameters before conception. In this study populace these specific measurements were not routinely repeated during pregnancy.

Several additional maternal obstetric and demographic characteristics known to influence birth weight are listed in Table II. Data on maternal hematocrit and random postprandial resting blood glucose level in late pregnancy are also included. The only significant between-group difference was pregnancy weight gain, which was 2.9 kg less in the exercise group. As the women who performed aerobics experienced only a minimal decrease in weight gain (overall weight gain 15.3 ± 4.1 kg), the difference was mainly due to a decrease in pregnancy weight gain in the runners (overall weight gain 12.1 ± 3.7 kg). On the basis of subjective recall data, these differences in weight gain did not appear to be due to a different pattern of change in dietary intake or in the amount of dietary intake at any point in time in the two groups, which were roughly equivalent over the course of pregnancy.

Maternal exercise performance. Before conception, running performance ranged between 16 and 68 km each week at a pace between 4.3 and 6 min/km and an intensity ranging between 51% and 83% of maximum. The average weekly duration-intensity index for the runners was 14,860 ± 353 (mean ± SD). During pregnancy, individual performance was quite variable but, as a group, overall running performance fell progressively until the sixth lunar month and then stabilized for the remainder of the pregnancy. Individual performance ranged between 50% and 109% of preconceptional levels for the entire pregnancy with an average of 69% ± 16%. In the last five lunar months it averaged 65% ± 18% of preconceptional levels with individual performances ranging between 50% and 122%.

Before pregnancy, participation in aerobics ranged between 3 and 11 sessions per week with a median of 4. Exercise intensity during warm-up and cool-down ranged between 20% and 40% of maximum and 54% to 90% of maximum capacity during the 25- to 30-minute so-called "aerobic" phase of the workout. The average duration-intensity index of 12,372 ± 311 was slightly less than that seen in the runners. During pregnancy the pattern of overall aerobic performance was similar to that seen with running, and individual variation was again the rule rather than the exception. In-

dividual performance ranged between 50% and 98% of preconceptional levels for the entire pregnancy with a group average of 67% ± 13%. In the last five lunar months it averaged 64% ± 13% of preconceptional values with individual performance ranging between 50% and 92%.

Before pregnancy the control women ran, performed aerobics, or participated in racquet sports intermittently at a frequency that ranged between two and eight times per month. The preconceptional duration-intensity index averaged 2936 ± 284 with the highest individual value being 6440. During pregnancy the majority stopped exercise completely before or shortly after confirmation of viability (n = 37), while the remainder continued to play racquet sports infrequently (once a week or less). In the latter, the weekly duration-intensity index ranged between 0 and 1550 after the end of the first trimester, with only three subjects consistently exceeding a weekly duration-intensity index of 1000 for >1 week each month.

Neonatal morphometrics. These data are detailed by group and subgroup in Tables III to V. Note that, whereas length, head circumference and placental weight were similar in the two groups, birth weight, birth weight percentile, ponderal index, its percentile, and the fetoplacental weight ratio all were decreased in the offspring of the women who continued to exercise throughout pregnancy. These differences are consistent with a pattern of brain-sparing, soft-tissue growth restriction, or so-called late-onset intrauterine growth restriction,[16] and appear more marked in the offspring of the runners than in the offspring of those who performed aerobics (Table IV).

The higher head circumference/abdominal circumference ratio and the lesser skin-fold thickness in the offspring of the exercising women (Table V) also are consistent with this pattern of intrauterine growth restriction and suggest that a large fraction of the difference in birth weight may simply be a reduction in fat mass in the offspring of the exercising women. Linear regression of estimated fat mass and birth weight supports this suggestion. There is a strong, direct relationship between fat mass (calculated from skin folds) and birth weight in the entire populace (r = 0.8050), such that the weight of neonatal fat explains approximately 65% of the variability in birth weight over a birth weight range between 2780 and 4120 gm. Indeed, differences in calculated body fat explain >70% of the difference in birth weight between the control infants and those of the women who continued to exercise throughout pregnancy. In the aerobics subgroup it explains 99% of the difference and in the running subgroup 60% (Table V).

Neonatal course. No infants in either group had an abnormal Dextrostix screening and, despite the differences in fat mass, only one infant in each group had a rectal temperature <36.0° C in the immediate neonatal period. Hematocrits were not routinely obtained and all infants left the hospital within 72 hours of birth.

Correlation between exercise performance and birth weight. As detailed in Table VI, there was no correlation between exercise performance before con-

ception and birth weight. The same was true for the absolute amount of exercise performed during any portion or all of pregnancy in the women who continued to exercise regularly, with the highest R^2 being 0.0032. However, when exercise performance during pregnancy was expressed as a percentage of that performed before conception, there was a significant but weak linear correlation between the overall relative level of exercise performance during pregnancy and birth weight. The correlation improved when it was corrected for the stage of pregnancy in which the exercise was performed and exercise type, indicating that exercise in late pregnancy and running had the most significant quantitative effects. Thus the relative level of exercise performance in the latter half of pregnancy explained approximately 40% of the variance in the birth weight of runner's offspring over an 1100 gm birth weight range. Additional least-squares analysis with the use of a power function fit improved this correlation slightly ($R^2 = 0.4437$). In contrast, although the offspring in the aerobics group were >200 gm lighter than the control infants, neither the absolute level nor the relative level of aerobic exercise performance during pregnancy correlated with the birth weight of the offspring.

Additional correlates with birth weight. Multiple potential confounding variables were also assessed for a possible association with birth weight. Significant correlations included placental weight ($R^2 = 0.0654$) and pregnancy weight gain ($R^2 = 0.2677$) for the entire populace. In the exercise group these correlations improved to $R^2 = 0.1106$ and $R^2 = 0.4356$ for placental weight and pregnancy weight gain, respectively. Additional potential confounding variables either were uniform within the populace (gestational age, smoking, socioeconomic and nutritional status) or had an $R^2 < 0.03$ when examined individually (preconceptional weight, height, parity, and sex of offspring). Therefore multiple regression analysis for factors influencing birth weight was limited to three independent variables in the running subgroup: relative exercise performance for the last 5 months of pregnancy, placental weight, and pregnancy weight gain.

Table VI. Correlations between exercise and birth weight

Exercise variable	*Exercise type*	R^2
Overall performance PTP	Both or either type	0.0002

Performance early preg.	Running	0.2174
Performance late preg.	Both types	0.1164
Performance late preg.	Running	0.4034
Performance late preg.	Aerobics	0.0027

Overall performance PTP, Average duration-intensity index before conception; *Overall performance TP*, average duration-intensity index during the total pregnancy divided by the average duration-intensity before conception; *Performance early preg.*, average duration-intensity index for the first five lunar months of pregnancy divided by the average duration-intensity before conception; *Performance late preg.*, average duration-intensity index for the last five lunar months of pregnancy divided by the average duration-intensity before conception.

Table VII. Fetoplacental weight ratios

Placental weight range (gm)	*Control ratio*	*Exercise ratio*
<400	9.75 ± 1.07	9.08 ± 0.74*
400-450	8.87 ± 0.88	7.76 ± 0.66*
451-500	7.54 ± 0.62	7.36 ± 0.43*
>501	7.32 ± 0.60	6.45 ± 0.44*

Data presented as mean ± SD.
*$p < 0.05$.

The addition of placental weight and pregnancy weight gain to the analysis explained only an additional 5% of the variance in birth weight ($R^2 = 0.4493$), suggesting that there were discrete associations between the three independent variables. The multiple correlation coefficients between birth weight and either placental weight combined with relative exercise performance or weight gain and relative exercise performance were similar (r values of 0.6341 and 0.6411, respectively), confirming that both placental weight and maternal weight gain, like birth weight, were independently related to running performance in the last 5

months of pregnancy. This was further substantiated by the correlations obtained between relative exercise performance over the latter half of pregnancy and both placental weight ($r = -0.3841$) and pregnancy weight gain ($r = -0.5881$). Thus in the running subgroup any birth weight effect of placental weight or pregnancy weight gain appeared to be due to the impact of running performance on each of them.

Exercise and the fetoplacental weight ratio. Although placental weight was similar in the two groups, the fetoplacental weight ratio was significantly decreased in the exercise group (Table II), suggesting that fetal growth per unit weight of placenta was restricted by exercise. To explore this possibility we calculated the fetoplacental weight ratio by placental weight in 50 gm increments. These data, shown in Table VII, demonstrate that the ratio is significantly decreased in the exercise group in all four weight groups. Linear regression of these data indicate that the slope of the relationship is similar in the two groups but that the intercept is reduced in the exercise group. As a result the average between-group difference in birth weight with placental weights between 300 and 600 gm averages 75 gm per 100 gm of placental weight.

Comment

At the outset it should be emphasized that these data were gathered from a select group of well-conditioned recreational athletes who had been performing two specific types of exercise on a regular basis for at least 2 years before conception and a similar select group of controls. Thus extrapolation of these findings to other groups of women and/or other exercise regimens is not warranted. With this limitation, these data strongly support the initial hypothesis, namely, that fetal growth is restricted when a regular running or aerobics program is maintained >50% of preconceptional levels during pregnancy. They also confirm the directional birth weight effect observed in earlier studies with runners and aerobic dancers in which an attempt was made to quantify exercise performance during pregnancy.[1, 4]

It is possible but unlikely that the differences in birth weight were due to differences in fitness between the two groups. First, while the control women spent much less time in exercise before conception, their level of fitness, as assessed by body composition, AM pulse rate, and maximum oxygen consumption, was not significantly different from that of the women who constituted the exercise group. Second, several studies that have assessed the effects of an exercise regimen on both fitness and birth weight have noted that fitness had either no effect or a positive effect on birth weight.[5, 8, 10] Third, as discussed in an earlier publication, others have noted a positive correlation between one measure of fitness during pregnancy, work capacity, and birth weight.[1] Finally, although not actually measured in the present study, the women who continued to exercise throughout pregnancy were probably more fit at the time of delivery and, if fitness were the important variable, they should have had heavier, not lighter, infants as compared with the control populace.

As discussed elsewhere,[16] the effect of caloric quality and quantity on birth weight is well known, but in the human, even with heavy physical activity, it appears to have a restrictive effect only when caloric intake is severely curtailed, and this is always associated with poor maternal weight gain.[17, 18] As the subjects in both groups experienced adequate weight gain (control, 16.4 kg; exercise, 13.5 kg) and by history followed diets of comparable quality, it is unlikely that dietary intake per se had a direct effect on the morphometric outcome.

The additional morphometric parameters indicate that the growth restriction appears limited to soft tissue and for the most part appears to be limited to a restriction of fat deposition, which is reassuring from a public health point of view. Further studies of body composition in similar infants with the use of more sophisticated technology (total body electrical conductivity) are planned to confirm these findings as are long term follow-up studies to determine if the decrease in fat mass at birth is maintained later in life. If so, this effect of regular exercise in pregnancy may have preventive value in terms of the risk of obesity in later life.

The data also demonstrate that different types of exercise and the time in pregnancy when the exercise is performed have different effects on neonatal morphometry and perhaps on other indices of pregnancy outcome. This is entirely consistent with the variable effects of exercise on various facets of pregnancy outcome reported with different exercise regimens to date,[1, 4-11] and indicates that each type of exercise and exercise regimen needs to be separately evaluated. The fact that a dose-response effect could be demonstrated with running and not with aerobics is a good example of this and requires clarification. However, the data obtained to date suggest that the two types of exercise may evoke different overall maternal physiological responses that may be related to the limited duration and variable intensity of aerobics versus running.[19] The observed reduction in neonatal fat mass with both forms of exercise is entirely consistent with a late pregnancy effect. Additional studies with exercise limited to either early or late pregnancy are needed to confirm this time-specific effect.

The finding of a consistent decrease in the fetoplacental weight ratio over more than a 250 gm placental weight range is of interest as it is quite different from that seen in a variety of animal models used to study fetal growth restriction.[16] In the animal model the ratio

is unchanged with mild and moderate degrees of restriction and increases with extreme growth restriction. Thus the decreased ratio associated with endurance exercise in the human may be indicative of a unique protective placental adaptation to the stimulus of recurrent fluctuations in uterine blood flow and/or substrate delivery. In any case it indicates that further study is warranted and must be conducted in the human.

In summary, the data obtained in this serial study of a relatively uniform, well-conditioned group of women support the initial hypothesis. In this populace they indicate that continuing aerobic and/or running regimens at or above a minimum training level in the latter half of pregnancy has a defined impact on fetal growth that is evidenced at birth by a reduction in birth weight that is primarily due to a reduction in neonatal fat mass. They also confirm that the interaction between the physiologic adaptations to exercise and the physiologic adaptations to pregnancy are multifaceted and warrant further study.

Does fasting interval affect the glucose challenge test?

Michael D. Berkus, MD,[a] Michael P. Stern, MD,[b] Braxton D. Mitchell, PhD,[b] Edward R. Newton, MD,[a] and Oded Langer, MD[a]

San Antonio, Texas

The relationship between fasting interval and glucose screening was assessed in a prospective study of 153 non-diabetic pregnant patients undergoing a standard 50g glucose challenge test. An interval of less than 3 hours after the last meal was found to be associated with a significantly greater insulin response as opposed to a fasting interval of more than 3 hours (121.3 pmol/l vs. 83.5 pmol/l, $p < .001$) and a greater insulin/glucose index (0.92 vs. 0.66, $p < .001$), with no difference in plasma glucose. Overall, obese patients had a higher glucose response than non-obese, but only higher insulin levels (107 pmol/l vs. 69 pmol/l, $p < .001$) and insulin/glucose index (0.79 vs. 0.59, $p < .02$) when the fasting interval was greater than 3 hours. Our data suggest that the fasting interval can influence insulin response during a glucose challenge test and the aberration in insulin secretion may effect screening results, especially in the high-risk gravida with glucose abnormality. (Am J Obstet Gynecol 1990;163:1812-7.)

Key words: Gestational diabetes, glucose screening, fasting interval, insulin, obesity

The American College of Obstetrics and Gynecologists Technical Bulletin recommended that a 50 gm oral glucose screening should be performed on all pregnant women 30 years of age or older, and on any women with risk factors such as a family history of diabetes or obesity. This screening should be performed between 24 and 28 weeks of gestation "without regard to time of last meal or time of day" and if the plasma glucose level measured 1 hour after the 50 gm load exceeds 140 mg/dl, a 3-hour oral glucose tolerance test should be administered.[1] Although extensive research has been performed regarding methods of glucose screening to determine the best threshold for identifying patients at risk for gestational diabetes,[2-4] a paucity of information exists as to the influence of a fasting or fed state on screening values,[5] and no study has examined the influence of fasting interval on insulin response to a glucose challenge test.

Previously, in the report of Coustan et al.,[5] it was found that the glucose response was significantly higher if patients with gestational diabetes had fasted than if they had been given a standard 600 kcal meal 1 hour before testing. They had hypothesized that the screening test value was lower in the fed state because previous ingestion of a mixed meal dampened the usual state of insulin resistance observed in fasting pregnant women.[5] They did not measure insulin levels in that study to confirm their hypothesis. The screening of pregnant patients after a standard meal may not be applicable to tests administered after the ingestion of unknown foodstuffs. Additionally, a 1-hour time interval may not be representative of other time intervals. Of significance is that examination of nonpregnant women with type II diabetes has shown an effect of protein loading on plasma glucose response to a 50 gm screening test after 4 hours and no significant effect at 1 hour. Also, the insulin response after a mixed loading was much greater than after a 50 gm glucose challenge alone.[6] Finally, Cheney et al.[7] have shown that obese women with gestational diabetes manifest higher glucose and insulin values after a 400 kcal breakfast meal, as compared with nonobese patients with gestational diabetes.

Thus it seems that pregnant patients with gestational diabetes respond to a glucose challenge test differently whether they are in the fasting or fed state and that this response is further modified by maternal size. However, it is not clear in subjects with an elevated screening result but a normal oral glucose tolerance test result to what extend insulin resistance plays a role in insulin response. Furthermore, there is no information regarding the relationship of fasting interval and obesity with glucose and insulin secretion when only the glucose challenge test result is abnormal.

Since the recommendation is to screen patients with a glucose challenge test without regard to timing or content of the last caloric intake, we chose to study mothers under this guideline[1] to discern the impact on screening results. Thus the purpose of this study was to examine the effect of fasting interval on glucose and insulin response to a glucose challenge test, to ascertain the influence of obesity and fasting interval on screen-

ing results, and to determine whether alterations in glucose and insulin secretion seen in women with gestational diabetes are present with minor degrees of glucose abnormality.

Material and methods

Nonhypertensive pregnant women were recruited from the obstetrics clinic of The University of Texas Health Science Center at San Antonio (UTHSCSA) and from other San Antonio–area clinics. The subjects were between 24 and 28 weeks of gestation or late registrants after 28 weeks and were not receiving insulin at the time of the study. The subjects included presumed normal pregnant women about to undergo a routine 50 gm glucose screening for gestational diabetes. Patients were enrolled without regard to their fasting state on an availability basis. The study was approved by the Institutional Review Board of the UTHSCSA and all subjects gave informed consent.

Body mass index was calculated as weight (in kilograms) divided by height (in meters) squared. For the purpose of analysis patients were considered to be obese if their body mass index was ≥27. Patients' glucose screening results were considered to be normal if the values were <140 mg/dl, to be abnormal if the values were ≥140 mg/dl, and to have gestational diabetes when two values on the oral glucose tolerance test were abnormal. Those mothers with gestational diabetes were excluded from the analysis. The patients were asked the number of hours since they had last eaten or drunk liquids other than water to determine the fasting time–to–screening interval. This value was then used as the fasting interval for the study. All testing was completed during morning clinics.

Blood samples were drawn 1 hour after a 50 gm load of a glucose equivalent (Koladex or Orangedex, Custom Laboratories, Baltimore) was administered. Plasma glucose level was determined with the use of the glucose oxidase method measured with a Paramax chemistry analyzer (American Dade Chemical Systems, Irvine, Calif.). Serum insulin concentrations were measured with a commercial solid-phase radioimmunoassay procedure (Diagnostic Products, Los Angeles). The coefficient of variation between duplicate aliquots measured at the same time was 8.1% for the 1-hour concentrations of insulin.[8] The insulin/glucose index was calculated to adjust for differing glucose levels.

Data analysis included bivariate and multivariate statistical techniques with parametric and nonparametric tests. Categoric data were analyzed with χ^2 and Fisher's exact tests. Continuous data were analyzed by Student's t test. One-way analysis of variance was used to compare different fasting intervals.

Results

A total of 163 patients participated in this prospective study. There were 119 women with a normal glucose screen (<140 mg/dl) and 44 with a glucose value ≥140 mg/dl. Of the 45 subjects with an abnormal screen, 10 had two abnormal values on the oral glucose tolerance test and were excluded from the analysis; this resulted in a total of 153 patients for evaluation.

Examination of fasting intervals of all subjects by means of analysis of variance for hourly groupings yielded significant differences for insulin and insulin/glucose index levels but not for plasma glucose values (F = 4.28, 5.47, and 0.16, respectively) (Table I). Subsequent post hoc t tests between hourly mean insulin response values yielded significantly greater values between 0 and 1 hour, 1 and 2 hours, and 2 and 3 hours and intervals >3 hours but no differences between intervals of 0 to 1 hour, 1 to 2 hours, or 2 to 3 hours. Therefore for the purpose of analysis the patients were stratified into two groups by a fasting interval of 0 to 3 hours, representing the "fed" patients, and ≥3 hours, representing "fasting" patients.

As shown in Table II, there were no significant demographic differences between groups, i.e., the "fed" group that ate within 3 hours of the test and the "fasting" group that had eaten 3 to 20 hours before being screened. All the patients were from the routine obstetrics clinic and were of similar age, parity, racial composition, gestational age, incidence of obesity, incidence of abnormal screening results, and plasma glucose level. Notably, both insulin level and the insulin/glucose index were significantly elevated in the "fed" group (<3 hours). The differences in insulin response were due

Table II. Patient characteristics and effect of 3-hour fasting interval

	"Fed" (mean = 1.6 ± 0.8 hr) (n = 69)	*"Fasting" (mean = 10.9 ± 5.0 hr) (n = 84)*	*p Value*
Age (yr)	25.0 ± 6	23.6 ± 5	NS
Primiparous (%)	6.5	3.9	NS
Multiparous (%)	38.6	51	NS
Hispanic (%)	32.7	39.9	NS
Gestational age (wk)	30.2 ± 5	29.6 ± 6	NS
Obesity (No.)	26 (37.7%)	29 (34.9%)	NS
Abnormal screen (No.)	18 (26.1%)	16 (19.0%)	NS
Glucose (mg/dl)	120 ± 26	120 ± 23	NS

Table III. Effect of 3-hour fasting interval on insulin response

	n	*"Fed" (< 3 hr)*	*"Fasting" (> 3 hr)*	*p Value*
Insulin (pmol/L)				
Normal (glucose < 140 mg/dl)	119	88 ± 43	82 ± 66	NS
Abnormal (glucose ≥ 140 mg/dl)	34	198 ± 101	94 ± 44	0.0006
Insulin/glucose index				
Normal (glucose < 140 mg/dl)	119	0.8 ± 0.4	0.7 ± 0.4	NS
Abnormal (glucose ≥ 140 mg/dl)	34	1.26 ± 0.6	0.6 ± 0.3	0.0004

entirely to patients with abnormal glucose screens (≥140 mg/dl) (Table III). As in insulin response the values for the corrected index (insulin/glucose) are significantly greater only for women with an abnormal screening.

Since obesity has been shown to have an influence on insulin resistance, the additional effect of obesity on glucose and insulin response was analyzed. The glucose response was higher for obese patients when the fasting interval was >3 hours (Fig. 1). Dividing glucose response for normal and abnormal glucose groups yielded significantly elevated values only for the normal "fasting" obese group. The insulin response in obese patients was greater than in nonobese women but only for the "fasting" group (Fig. 2). This was true whether the glucose screening was normal (<140 mg/dl) or abnormal. Also, for nonobese or lean patients in the abnormal group, the insulin response was significantly more for "fed" lean than "fasting" lean mothers, despite the small number of patients in these categories. When the insulin/glucose index or ratio was examined, the significance pattern was similar; however, the difference in the abnormal "fasting" group (glucose ≥140 mg/dl) was only marginally significant for obese versus lean (0.73 ± 0.3 vs 0.53 ± 0.2, $p = 0.09$) (Fig. 3).

Comment

A screening test should reliably detect individuals at risk for a disease in a safe, inexpensive, and convenient manner. The 50 gm oral glucose challenge test has been shown to meet these criteria.[2] Giving the test without regard to time of last meal adds to the convenience of the test and allows for more rapid assessment when necessary in advanced gestation. However, no previous studies have attempted to determine the effect, during glucose screening, of a variable time interval from the last meal on glucose and insulin results. This is the first report of the insulin response to a glucose challenge under the recommendation of The American College of Obstetricians and Gynecologists.[1]

The key findings in this study support the concept that the fasting interval can influence insulin response during a glucose challenge test and that maternal size may further modulate this effect. A fasting interval of up to 3 hours was found to be the critical interval in this study. Stratifying the data according to these results (<3 hours and ≥3 hours) yielded significant differences in insulin but not in glucose response. This difference was present only in the abnormal screening group, i.e., plasma glucose level ≥140 mg/dl. Obese subjects did have higher plasma glucose values than nonobese women when "fasting" and also had a greater insulin response than lean patients when the fasting interval was ≥3 hours. When the glucose screen was abnormal, both obese and nonobese gravid women had decreased insulin response ≥3 hours or more after eating. When the screen was normal (glucose <140 mg/dl), only lean subjects had a decreased response when "fasting."

Thus fasting interval did affect insulin response and resistance as reflected by the insulin/glucose index, and obesity further modified the results. The final question addressed by the study was to determine whether the

glucose and insulin response found in women with gestational diabetes was present in patients with only minor glucose abnormality, i.e., only aberrant results of the glucose challenge test (the abnormal group in this study). As there were insufficient cases of diabetes in our original sample to have the statistical power necessary for an adequate comparison, data were gathered from the current literature for this evaluation.

Coustan et al.[3] found a significantly lower plasma glucose screening value when the 50 gm challenge was

administered 1 hour after a standard 600 kcal meal was eaten, but this was true only in subjects known to have gestational diabetes. They hypothesized that this lower value occurred in the "fed" state as compared to the "fasting" state because eatng had "dampened" the normal insulin resistance. We found the insulin resistance, as reflected by the insulin/glucose ration, to be increased in the "fed" mothers in our abnormal group, but there was no difference in the glucose response of "fed" versus "fasting" gravid women. Thus patients with only an abnormal glucose challenge test behaved similarly to the "presumed normal" patients in the study of Coustan et al., i.e., with no difference in glucose response, but they had increased insulin values probably because of the protein present in their last meal. A dampened insulin resistance was not seen; rather the "fed" subjects with gestational diabetes most likely received stimulation to produce more insulin. This lowered the glucose level significantly, but not to the level of the normal patients, as reflected by higher glucose values (154.8 ± 24.1 vs 115.8 ± 23.4 gm/dl) in that study.[5]

In a well-done study by Nuttall et al.[6] untreated, nonpregnant individuals with diabetes were given mixed protein and glucose meals. With increasing protein supplement, they found greater insulin response without any increase in glucose level. Clearly, screening soon after a mixed meal, including protein, as may have occurred in the "fed" group of this study, could explain the increased insulin response obtained. This effect of protein would necessarily be prolonged in pregnancy, as a result of the increased gastric emptying time, and this physiologic phenomenon might explain the 3-hour stratification found in this report.

Cheney et al.[7] studied obese and nonobese women with gestational diabetes after a standard 400 kcal mixed meal. They found significantly increased glucose and insulin levels for obese patients with gestational diabetes but decreased insulin levels in lean women with gestational diabetes when compared with normal subjects. They concluded that the obese patients with gestational diabetes had increased insulin resistance, whereas the lean patients with gestational diabetes had insulin deficiency. Catalano et al.[9] showed that this resistance was present even after delivery when obese subjects with gestational diabetes were tested with the hyperinsulinemic-euglycemic clamp. In our study the "fed" patients are similar to the post-mixed-meal patients of Cheney et al. In the abnormal group, glucose, insulin, and insulin/glucose index (i.e., insulin resistance) were increased as compared with values in normal gravid women. This was true for both obese and lean patients in this group. Thus the lean patients with minor glucose abnormalities in our study did not show any deficiency in insulin response.

A number of investigators[10-14] have shown that insulin sensitivity declines when an individual becomes obese. Ryan et al.[15] demonstrated, by means of euglycemic glucose clamp techniques, that nondiabetic pregnant patients have increased insulin resistance over non-

pregnant ones, and gestational-onset diabetic women have even greater resistance. The findings in this study of increased insulin and insulin/glucose index in obese patients in the "fasting" group are consistent with these findings. The relatively greater increase in insulin response of nonobese patients, when "fed," seemed to overshadow the effect of obesity, even in the group with glucose values ≥140 mg/dl, where both obese and lean patients have increased insulin output. Thus the "fed" state increased the insulin response to a greater extent than obesity altered insulin resistance in these mothers with minimal glucose abnormalities.

In summary, when compared with patients who undergo a standard oral 50 gm glucose challenge test after a fasting interval of >3 hours, pregnant women who have eaten more recently ("fed" women) have a greater insulin response if the glucose screening level is ≥140 mg/dl, whereas obese subjects have evidence of increased insulin resistance only when "fasting," regardless of glucose level.

Relationships between glucose levels and insulin secretion during a glucose challenge test

Michael D. Berkus, MD,[a] Michael P. Stern, MD,[b] Braxton D. Mitchell, PhD,[b] Aida Abashawl, BS,[b] and Oded Langer, MD[a]

San Antonio, Texas

The relationship between glucose and insulin levels was examined in a prospective study of 153 pregnant patients without diabetes who underwent a standard 50 gm glucose challenge test. One hundred eighteen women had normal screening results (glucose level <140 mg/dl) and 35 had abnormal screening values but a normal oral glucose tolerance test. Abnormal responders had greater insulin levels (149 vs 82 pmol/L, $p < 0.0001$), and a higher insulin/glucose index (0.96 vs 0.72, $p < 0.007$). Patients with glucose levels <100 mg/dl had significantly lower insulin/glucose indices. Overall, obese patients had significantly greater glucose and insulin measurements than did nonobese women, but there was no difference within normal and abnormal groups. Glucose levels accounted for 52% of the insulin output and 29% of the insulin/glucose index variance. Neither age, parity, nor obesity contributed significantly to insulin levels in the multiple regression model. Therefore the accepted threshold for glucose screening reflects abnormal insulin output and this aberration may be indicative of the primary defect in gestational diabetes. (Am J Obstet Gynecol 1990;163:1818-22.)

Key words: Diabetes screening, minimal glucose abnormality, insulin output

The concept of screening for gestational diabetes with the glucose challenge test is well established.[1-4] In addition, there appears to be a positive association between the glucose challenge test and glucose profile in pregnancy, with a significantly higher profile in the abnormal screening group. However, minimal information exists as to the basic endocrinologic significance of an abnormal glucose challenge test.

It has become axiomatic that obesity is associated with diabetes as a result of insulin resistance.[5-8] It is this resistance that may result in both type II diabetes and gestational diabetes mellitus. Tissue sensitivity to insulin has been found to decline by approximately 30% to 40% when an individual exceeds 35% to 40% of ideal body weight.[7] This insulin resistance primarily affects muscle and involves both oxidative and nonoxidative pathways of glucose disposal. However, the unanswered question remains: What is the effect of obesity on insulin secretion in minor degrees of glucose abnormality in pregnancy, reflected by an abnormal glucose challenge test in the presence of a normal oral glucose tolerance test?

The purpose of this study was to examine the effect of glucose level on insulin output during a glucose challenge test, to ascertain the additional influence of obesity on this output, and to determine whether alterations in glucose and insulin values previously reported in gestational diabetes[9, 10] are present in cases with only minor degrees of glucose abnormality.

Material and methods

Nonhypertensive pregnant women were recruited from the obstetrics clinic of The University of Texas Health Science Center at San Antonio and from other San Antonio area clinics. The subjects were between 24 and 28 weeks' gestation or late registrants after 28 weeks and were not receiving insulin at the time of the study. The subjects included women with presumed normal pregnancies about to undergo screening for gestational diabetes. The study was approved by the institutional review board of the university and all subjects gave informed consent.

Body mass index was calculated as weight (in kilograms) divided by height (in meters) squared. For the purpose of analysis, patients were considered to be obese if their body mass index was ≥27. A patient's glucose screening was considered to be normal if the values were <140 mg/dl and abnormal if the values were greater; the patient was considered to have gestational diabetes mellitus when at least two values on the oral glucose tolerance test were abnormal. All testing was completed during morning clinics.

Blood samples were drawn 1 hour after a 50 gm load of a glucose equivalent (Koladex or Orangedex, Cus-

tom Laboratories, Baltimore) was administered. Plasma glucose was determined by the glucose oxidase method and was measured with a Paramax Chemistry Analyzer (American Dade Chemical Systems, Irvine, Calif.). Serum insulin concentrations were measured with a commercial solid-phase radioimmunoassay procedure (Diagnostic Products, Los Angeles). The coefficient of variation between duplicate aliquots measured at the same time was 8.1% for the 1-hour concentrations of insulin.[11] The insulin/glucose index was calculated to adjust for differing glucose levels.

Data analysis included bivariate and multivariate statistical techniques with parametric and nonparametric tests. Categoric data were analyzed with Fisher's exact and χ^2 tests. Continuous data were analyzed by the Student t test. One-way analysis of variance was used to compare different levels of glycemia. The association between variables was determined by calculating Pearson's correlation coefficients.

A stepwise multiple regression was performed to determine the extent to which the variables contributed to insulin secretion. Both tests of significance and the magnitude of the relationships, expressed as the variance of the dependent variable that could be accounted for by the independent variable, were used to report regression results. Variables contributing 3% of the total variance were considered worthwhile. In all cases, the F values were significant at the 0.01 level.

Results

A total of 171 patients participated in this prospective study. The group consisted of pregnant patients undergoing a routine 50 gm glucose screening for gestational diabetes, as outlined by the American College of Obstetricians and Gynecologists.[12] Patients were enrolled on an availability basis. Missing data were as follows: Four patients did not obtain the glucose screening and four additional subjects did not have insulin levels measured. A total of 163 complete data sets were available for analysis. There were 118 women with normal glucose screens (<140 mg/dl) and 45 with glucose values ≥140 mg/dl. Of the 45 subjects with abnormal screens, 10 had gestational diabetes mellitus. Those women with gestational diabetes mellitus were excluded from the analysis.

>160	11	158.5 ± 137	0.92 ± 0.8

*Insulin: (Glucose <100) versus (Glucose ≥100), $p < 0.01$.

†Insulin/glucose index: (Glucose <100) versus (Glucose ≥100), $p < 0.02$.

‡Insulin: (Glucose 100 to 119) versus (Glucose ≥120), $p < 0.04$.

§Insulin: (Glucose 120 to 139) versus (Glucose ≥140), $p < 0.02$.

There were no significant differences in demographic characteristics between the normal and abnormal glucose groups (Table I). The abnormal responders had a greater insulin level, as would be expected; in addition, they had significantly greater insulin/glucose index values.

Examination of levels of glycemia of all subjects, by means of analysis of variance for 20 mg/dl groupings, yielded significant differences for insulin ($F = 14.22$) and insulin/glucose index ($F = 4.60$) (Table II). Subsequent posthoc t tests between mean insulin values showed significantly lower values between each of the glucose groupings <140 mg/dl and higher glucose levels, but no differences for the groups ≥140 mg/dl. The t tests between mean insulin/glucose index values generated significantly lower values for only the group of women with glucose values <100 mg/dl. Thus this subgroup of low glucose reactors had relative hypoinsulinemia.

Overall, obese gravid women had significantly greater glucose and insulin serum levels than did non-

Table III. Association between insulin secretion and maternal size

	Nonobese (n = 97)	*Obese (n = 56)*	*p Value*
Insulin (pmol/L)	87.1 ± 60	114.2 ± 76	0.02
Insulin/glucose index	0.72 ± 0.4	0.87 ± 0.5	0.053
Glucose	117 ± 24	127 ± 25	0.01

obese subjects, but only a marginally greater insulin/glucose index (Table III). Although there were significant differences in insulin levels between groups for both obese and nonobese women, obesity had no differential effect on the insulin/glucose index within the groups, and only a marginally significant increase in glucose and insulin values for women with glucose levels <140 mg/dl (Table IV).

There was a relatively strong association between glucose and insulin level as determined by Pearson correlation ($r = 0.54$, $p < 0.0001$), and a significant but less strong association between glucose and insulin/glucose index ($r = 0.31$, $p < 0.0001$), glucose and body mass index ($r = 0.21$, $p < 0.01$), and body mass index and insulin level ($r = 0.17$, $p < 0.04$). There was no association between body mass index and insulin/glucose index.

Stepwise multiple regression was performed to determine the relative contribution of glucose, body mass index, parity, and age to insulin values. Only the level of glycemia had a significant F value, and accounted for 52% of the total variance in insulin level and 29% of the insulin/glucose index variance. None of the other variables, including body mass index, contributed significantly to the insulin values in the multiple regression model.

Comment

The major finding of this study was that patients with abnormal glucose screening during a 50 gm glucose challenge test had increased insulin output, even after adjustment for glucose values. This was true for both the normal and abnormal screening groups. There was a significantly lower insulin value among subjects with screening glucose values <100 mg/dl. The insulin levels within the group with values <140 mg/dl were otherwise indistinguishable, as were the responses of subjects with glucose levels >140 mg/dl. Furthermore, multivariant analysis failed to show any contribution of age, parity, or maternal size to the insulin values of either group.

Increased insulin resistance in patients with type II diabetes has been shown conclusively by use of insulin-clamp techniques.[13] The same methods have been used to demonstrate increasing resistance in pregnancy: nondiabetic pregnant patients have increased resistance over nonpregnant women, and women with gestational onset diabetes have even greater impairment.[14] Researchers also have found increased insulin resistance that persisted post partum in obese women with gestational diabetes mellitus even when standard measures of glucose tolerance were normal.[10] Whether these differential effects are present during a pregnancy with only minor degrees of glucose abnormality has not been addressed.

The results of this study support the concept that there is heightened insulin output in patients with abnormal glucose challenge test results over pregnant patients with glucose values <140 mg/dl, even if the oral glucose tolerance test is normal. The increased insulin/glucose index also was consistent with previous reports of increased insulin resistance. Bivariate analysis yielded only a marginally significant contribution of obesity to glucose and insulin measurements. However, this relationship was not independent of glucose level because multivariate analysis failed to show any additional contribution of maternal size to insulin secretion or resistance, as evidenced by the insulin/glucose index in patients with minimal glucose abnormality. In addition, there was relative hypoinsulinemia among the patients with glucose screening values <100 mg/dl. In this group, there was significantly less insulin measured, even when adjusted for the glucose values. This may represent compensatory mechanisms to facilitate glucose transfer to the fetus, even in mothers with low levels of serum glucose. There are recent reports that high-risk patients with hypoglycemic-hypoinsulinemia are at increased risk for small-for-gestational-age infants.[15]

Although there is evidence that maternal age is a risk factor for gestational diabetes mellitus,[12] no such association was found in this investigation for patients with lesser glucose aberration. Current research has shown a slight increase in the risk of noninsulin-dependent diabetes mellitus or impaired glucose tolerance with increasing parity many years after childbearing, independent of obesity.[16] Neither of these factors contributed significantly to the insulin output in this study during pregnancy. Thus there was no evidence that these variables had an impact on insulin levels during the glucose challenge test in women with only minor degrees of glucose abnormality, with only glucose level remaining as the main determinant.

The threshold of 140 mg/dl for glucose abnormality in the glucose challenge test is well established.[3, 4, 12] The underlying endocrinopathy of that recommendation is not so apparent. Our study attempted to uncover the

Table IV. Association between maternal size, glucose screening level, and insulin response

	Nonobese	*Obese*	*p Value*
Normal (<140 mg/dl)	$n = 79$	$n = 39$	
Insulin (pmol/L)	75.5 ± 44	93.7 ± 54	0.056
Insulin/glucose index	0.68 ± 0.4	0.8 ± 0.4	NS
Glucose (mg/dl)	108 ± 16	114 ± 16	0.06
Abnormal (≥140 mg/dl)	$n = 18$	$n = 17$	
Insulin (pmol/L)	138 ± 89	161 ± 98	NS
Insulin/glucose index	0.89 ± 0.6	1.02 ± 0.6	NS
Glucose (mg/dl)	155 ± 12	158 ± 12	NS

basis for this threshold and provide a physiologic rationale for the choice of such a value. The differential insulin production discovered in the abnormal screening group, present in even minimal glucose divergence, may offer an explanation.

Recently it has been proposed by several investigators that even "relative hyperglycemia" in nondiabetic subjects is associated with an increased adverse outcome, primarily macrosomia. Tallarigo et al.[17] found that even limited degrees of maternal hyperglycemia were associated with a significant increase in the incidence of macrosomia, congenital abnormalities, toxemia, and cesarean section. Langer et al.[18] found that gravid subjects with one abnormal value on an oral glucose tolerance test had daily glucose profiles comparable to those of women with gestational diabetes mellitus, and this profile was significantly higher than that of normal nondiabetic mothers. Moreover, the incidence of macrosomia has been found to be significantly greater in patients with one abnormal glucose value when compared with treated subjects with gestational diabetes mellitus (24% vs 6%,[18] 18% vs 6.6%[19]). Leikin et al.[20] also determined that patients with minor abnormalities of carbohydrate metabolism (glucose levels ≥135 mg/dl on a glucose challenge test) were at increased risk for delivery of a macrosomic infant.

Therefore it is evident that even minor glucose abnormalities are associated with fetal macrosomia, a classic complication related to glycemic level, as proposed by the Pedersen theory.[21] Presumably, patients with these abnormalities have elevated insulin levels and probably increased insulin resistance. However, it has not been shown that these subjects have a basic insulinopathy. Our data are consistent with the existence of an insulin defect in even minor degrees of glucose deviation.

Consequently, this study offers evidence that glucose abnormality is a continuum associated with abnormal insulin levels that becomes increasingly evident with greater degrees of glucose aberration. Moreover, it appears that the current threshold for glucose screening does reflect significant differences in insulin output that may underlie the basic endocrinopathy of gestational diabetes mellitus. Further research is needed to substantiate these observations.

Effect of low-dose oral contraceptives on carbohydrate and lipid metabolism in women with recent gestational diabetes: Results of a controlled, randomized, prospective study

Siri L. Kjos, MD, Donna Shoupe, MD, Sylvie Douyan, MD, Richard L. Friedman, MD, Gerald S. Bernstein, MD, Jorge H. Mestman, MD, and Daniel R. Mishell, Jr., MD
Los Angeles, California

Women with recent gestational diabetes mellitus were randomly assigned to one of two low-dose oral contraceptives to evaluate the effect of low-dose oral contraceptives on carbohydrate and lipid metabolism. A cohort of similar women requesting a non-oral-contraceptive method served as controls. The two oral contraceptives studied were ethinyl estradiol (0.035 mg)–norethindrone (0.40 mg) and ethinyl estradiol (0.030 to 0.040 mg)–levonorgestrel (0.050 to 0.125 mg). A 75 gm, 2-hour oral glucose tolerance test and a fasting lipid profile (total cholesterol, triglyceride, high- and low-density lipoprotein cholesterols) were performed at entry, after 3 months, and after 6 to 13 months of treatment. The prevalence of diabetes at 6 to 13 months (27/156 patients) was not significantly different between groups (non-oral-contraceptive group, 17%; ethinyl estradiol–norethindrone, 15%; ethinyl estradiol–levonorgestrel, 20%). When examined by prior gestational diabetes mellitus class, diabetes mellitus was present in 7% of prior class A_1 and 29% of women with prior class A_2 disease ($p < 0.001$). Mean cholesterol and low-density lipoprotein cholesterol levels were significantly improved in all three groups at 3 months and at 6 to 13 months, whereas triglycerides remained unchanged. There were no differences in cholesterol, low-density lipoprotein cholesterol, or triglycerides levels between the groups. After 6 to 13 months, there was a significant increase in high-density lipoprotein cholesterol in the ethinyl estradiol–norethindrone group compared with the ethinyl estradiol–levonorgestrel and non-oral-contraceptive groups. (Am J Obstet Gynecol 1990;163: 1822-7.)

Key words: Gestational diabetes mellitus, low-dose oral contraceptives, lipids, glucose tolerance

Determination of the metabolic effect of oral contraceptives in women with prior gestational diabetes is complicated by inherent deterioration in carbohydrate tolerance. Within 15 years of the diagnosis of gestational diabetes mellitus, diabetes mellitus will develop in more than half of these women, with those who required insulin during pregnancy at greatest risk.[1-3] Earlier reports of high-dose oral contraceptive use in women with prior gestational diabetes mellitus show marked deterioration in glucose tolerance.[4,5] The dose and potency of the progestin component of oral contraceptives appear to decrease glucose tolerance, increase insulin resistance, and adversely affect cholesterol, whereas estrogen appears to counterbalance these changes.[6-9] By decreasing both the estrogen and

progestin dose, newer low-dose oral contraceptives have little or no effect on carbohydrate and lipid metabolism in healthy women.[10-16] Two recent 6-month studies address low-dose oral contraceptive use in women with prior gestational diabetes mellitus. One study shows no change in glucose tolerance, insulin, or lipid levels,[17,18] whereas the other demonstrates an increase in glucose and insulin levels.[19]

This study evaluates the effect of short-term usage (6 to 13 months) of two randomly assigned low-dose oral contraceptives on carbohydrate and lipid metabolism in postpartum women with recent gestational diabetes mellitus. The metabolic status of these women is compared with that of a similar cohort of women who also had recent gestational diabetes mellitus, but who chose form of birth control other than OCs. This study design allows the determination of whether postpartum deterioration of carbohydrate or lipid metabolism is inherently related to the disease process alone or whether there is an additional deleterious effect from oral contraceptive use.

Material and methods

Subjects. A total of 230 patients were studied. All had recent gestational diabetes mellitus diagnosed by two or more abnormal values during a 100 gm 3-hour oral glucose tolerance test during pregnancy.[20] Of these women, 95% were of Latin American origin or descent. Patients were subclassified according to their degree of fasting hyperglycemia during pregnancy. Patients with class A_1 disease (N = 124) maintained fasting serum glucose levels below 105 mg/dl. Patients with class A_2 disease (N = 106) had at least one fasting serum glucose level ≥105 mg/dl.[21] Postpartum patients underwent entry glucose tolerance testing (mean time from delivery to entry test, 49 days). Those patients diagnosed with diabetes mellitus were excluded from study entry. Patients desiring oral contraceptives were randomized to receive either a monophasic preparation of 0.40 mg norethindrone and 0.035 mg ethinyl estradiol (Ovcon 35, Mead Johnson, Evansville, Ind.) or a triphasic preparation of 0.050 to 0.125 mg levonorgestrel and 0.030 to 0.040 mg ethinyl estradiol (Triphasil, Wyeth, Philadelphia). These two preparations were chosen because they contain the lowest amount of the two progestins most commonly used in the United States. Patients who chose alternative methods were enrolled as non-oral-contraceptive controls without being randomized. Non-oral-contraceptive methods included barrier methods, the intrauterine contraceptive device, and tubal sterilization. All patients were counseled to continue the American Diabetes Association diet. The study protocol was approved by the Research Committee of the Los Angeles County–University of Southern California Medical Center.

Study design. Metabolic studies, consisting of a 2-hour oral glucose tolerance test and a fasting lipid profile (cholesterol, triglyceride, low-density lipoprotein cholesterol, and high-density lipoprotein cholesterol), were performed at entry, 3 months, and 6 to 13 months. Pill compliance, weight, and blood pressure were recorded at each visit. The diagnosis of diabetes mellitus at 3 months constituted a study end point that necessitated the discontinuation of oral contraceptives. These patients were not retested at 6 to 13 months.

Metabolic studies. After 3 days of a diet that provided at least 150 gm/day of carbohydrate, patients fasted overnight and then ingested 75 gm of glucose over 5 minutes. Blood specimens were obtained by venipuncture at −5, +30, +60, +90, and +120 minutes. Specimens were transported on ice for immediate separation of serum and cells. Serum was stored at −20° C for subsequent glucose measurement (model II glucose analyzer, Beckman Instruments, Fullerton, Calif.). Results were interpreted according to the National Diabetes Data Group definitions of diabetes mellitus and impaired glucose tolerance.[20] Glucose tolerance between study groups was also evaluated by integrating the total area under the glucose tolerance curve (gm · min/dl) over the 120-minute oral glucose tolerance test. Total cholesterol and triglyceride levels were measured by procedures that use enzymatic hydrolysis and oxidation (Olympus AU5061, Olympus Corp., New York). High-density lipoprotein cholesterol was determined by procedures using cholesterol oxidase, after sodium phosphotungsate precipitation of low-density lipoprotein cholesterol and very-low-density lipoprotein cholesterol (Beckman CX4). Low-density lipoprotein cholesterol was calculated as (Low-density lipoprotein cholesterol = Cholesterol − [high-density lipoprotein cholesterol + triglyceride/5]).[22]

Statistical analysis. Continuous variables (area under the curve, lipids, weight, etc.) within a study group or gestational diabetes mellitus class over time were analyzed by paired one-sample analysis; differences between groups were examined with two-sample analysis and analysis of variance. Differences between study groups or gestational diabetes mellitus classes with respect to glucose tolerance test status were tested for significance by χ^2, with adjustments for multiple comparisons when appropriate.

Results

Table I shows the demographic data comparing the study groups at entry. The non-oral-contraceptive patients are slightly older, heavier, and of higher parity. The mean body mass index (calculated as kg/m^2) is elevated in all three groups; a standard definition of overweight was used as body mass index ≥ 27 kg/m^2.[23] The percentage of the patients with prior class

Table I. Entry demographic data according to study birth control methods

	Study birth control method		
	Non-oral-contraceptive group (N = 67)	*Ethinyl estradiol–norethindrone (N = 80)*	*Ethinyl estradiol–levonorgestrel (N = 83)*
Age (yr)	31 ± 4	28 ± 5	29 ± 5
BMI (kg/m²)	31 ± 6*	29 ± 5	28 ± 5
Parity	3 ± 2	2 ± 1	2 ± 1
Class A_2	55%	38%	45%

Data recorded are mean ± SD. *BMI*, Body mass index—Weight/Height)². The non-oral-contraceptive methods included barrier methods, intrauterine contraceptive devices, and sterilization. The monophasic preparation consisted of 0.40 mg norethindrone and 0.035 mg ethinyl estradiol, and the triphasic preparation consisted of 0.050-0.125 mg levonorgestrel and 0.030 to 0.040 mg ethinyl estradiol.

*$p < 0.05$. For all other methods, p = ns.

A_2 gestational diabetes mellitus is not significantly different between the groups. The interval in days from the delivery data to the 6 to 13 months evaluation for each of the study groups was not significantly different (non-oral-contraceptive, 343 ± 120 days; ethinyl estradiol–norethindrone, 317 ± 102 days; ethinyl estradiol–levonorgestrel, 346 ± 149 days). This is important because the risk of developing diabetes after a pregnancy complicted by gestational diabetes mellitus increases with time after delivery.[1, 2]

No patients had hypertension (≥140/90 mm Hg) that necessitated discontinuation of oral contraceptives. Oral contraceptives were discontinued in four women after 3 months of use because of markedly elevated triglyceride levels (≥500 mg/dl). All four had elevated triglyceride levels post partum (≥300 mg/dl) that did not respond to diet therapy. One hundred fifty-six patients completed the testing at 6 to 13 months. Seventy women did not complete the study at 6 to 13 months because of self-discontinuation of oral contraceptives or loss to follow-up. These patients did not differ significantly in mean age (29 ± 5 years), parity (3 ± 1), body mass index (29 ± 5 kg/m²), entry area under the curve values (16.2 ± 4.0 gm · min/dl), or percent composition of prior class A_2 patients (42%).

Glucose tolerance. Table II shows the mean total area under the curve at entry, 3 months, and 6 to 13 months according to study groups. There was no significant difference in mean area under the curve between the three groups at each testing interval (entry, 3 months, and 6 to 13 months). When the data were analyzed within a group as a function of time, there was an increase in area under the curve during the study period. Paired one-sample analysis showed a significant increase in area under the curve for both oral contraceptive groups at 3 months and 6 to 13 months when compared with their entry area under the curve ($p < 0.04$). There was a similar, nonsignificant trend ($p = 0.06$) in the non-oral-contraceptive group. This analysis of area under the curve omitted the results of 6 to 13-month testing of patients with the highest 3-month area under the curve; women diagnosed with diabettes mellitus, as these 14 women (five in non-oral-contraceptive group, three in the ethinyl estradiol–norethindrone group, and six in the ethinyl estradiol–levonorgestrel group), were not retested.

The clinically more useful method of interpreting these findings was to use the glucose tolerance test status at 6 to 13 months, including the data of the 14 women diagnosed as having diabetes mellitus at 3 months (Table III). The prevalence of impaired glucose tolerance and diabetes mellitus was not significantly different among the three groups, irrespective of oral contraceptive use. In the non-oral-contraceptive patients, impaired glucose tolerance and diabetes mellitus each occurred in nine (17%) patients. Impaired glucose tolerance and diabetes mellitus were respectively present in five (11%) and seven (15%) patients in the ethinyl estradiol–norethindrone group and in eight (14%) and 11 (20%) patients in the ethinyl estradiol–levonorgestrel group. The overall prevalence of diabetes was 17% by 6 to 13 months.

Analysis of the 6- to 13-month oral glucose tolerance test status by gestational diabetes mellitus classification rather than by birth control method showed a significant relationship (Table IV). Both impaired glucosetolerance and diabetes mellitus were significantly more prevalent at 6 to 13 months in women with prior class A_2 gestational diabetes mellitus ($p = 0.03$ and $p < 0.001$, respectively). Among women in class A_2, 14 of 73 (19%) had impaired glucose tolerance and 21 (29%) had diabetes mellitus, whereas in patients with class A_1 disease, eight of 83 (10%) had impaired glucose tolerance and six (7%) had diabetes mellitus. A difference in carbohydrate metabolism between patients with class A_1 and A_2 disease was also evident at the entry test. In patients with prior class A_2 disease at entry, impaired glucose tolerance was found in 23 of 106 (21%) compared with eight of 124 (6.4%) of patients with prior class A_1 disease ($p < 0.001$). The entry area under the

¶A significant intergroup difference in high-density lipoprotein cholesterol exists: $p \leq 0.01$ versus non-oral-contraceptive and ethinyl estradiol–levonorgestrel high-density lipoprotein cholesterol at 6 to 13 months. Other differences between study groups within a testing interval are not significant.

Table III. Prevalence of normal, impaired, and diabetic glucose tolerance after 6 to 13 months of study birth control method in women with recent gestational diabetes mellitus

	6-13 mo oral glucose tolerance test status		
	Normal	*Impaired*	*Diabetic*
Non-oral-contraceptive method (n = 53)	35 (66%)	9 (17%)	9 (17%)
Ethinyl estradiol–norethindrone (n = 47)	35 (74%)	5 (11%)	7 (15%)
Ethinyl estradiol–levonorgestrel (n = 56)	37 (66%)	8 (14%)	11 (20%)
TOTAL	107 (69%)	22 (14%)	27 (17%)

Study groups are defined in Table I. Numbers in parentheses denote number of women who completed the study, including 14 women diagnosed with diabetes mellitus after 3 months of study. There are no significant intergroup differences in prevalence of glucose tolerance test status (p = 0.48).

curve of women with prior class A_2 gestational diabetes mellitus was correspondingly higher (18.4 ± 3.3 compared with 15.4 ± 3.0 gm · min/dl) ($p < 0.001$).

Cholesterol. There was a significant decrease in mean total cholesterol levels in all study groups when the 3-month and the 6- to 13-month levels were compared with the mean entry cholesterol level ($p < 0.001$, Table III). There was no significant difference between the study groups at each testing interval. The overall mean cholesterol at 6 to 13 months was 194 ± 34 mg/dl.

Low-density lipoprotein cholesterol. There was also a significant decrease in mean low density lipoprotein cholesterol levels at 3 months and at 6 to 13 months

Table IV. Prevalence of normal, impaired, and diabetic glucose tolerance after 6 to 13 months of study according to prior gestational diabetes classification

	6-13 mo oral glucose tolerance test status		
	Normal	*Impaired*	*Diabetic*
Class A_1 (n = 83)	69 (83%)	8 (10%)	6 (7%)
Class A_2 (n = 73)	38 (52%)	14* (19%)	21† (29%)
TOTAL	107 (69%)	22 (14%)	27 (17%)

Class A_1 and A_2 denote women with antepartum fasting serum glucose levels <105 and ≥105 mg/dl respectively. Numbers in parentheses denote the number of women in each group.

*p = 0.03 versus class A_1 impaired glucose tolerance.

†$p < 0.001$ versus class A_1 diabetes mellitus.

compared with entry levels in all three study groups ($p \leq 0.05$ and $p \leq 0.01$, respectively). The overall mean low density lipoprotein cholesterol level at 6 to 13 months was 121 ± 31 mg/dl.

High-density lipoprotein cholesterol. The mean high-density lipoprotein cholesterol was unchanged in both the non-oral-contraceptive and ethinyl estradiol–levonorgestrel groups throughout the study. In contrast, the 6- to 13-month mean high-density lipoprotein cholesterol level was significantly higher in the ethinyl estradiol–norethindrone group when compared with the mean entry high-density lipoprotein cholesterol level ($p < 0.01$). The mean high-density lipoprotein cholesterol level in this group was also significantly higher compared with the 6- to 13-month levels in the non-oral-contraceptive and ethinyl estradiol–levonorgestrel groups ($p \leq 0.01$).

Triglycerides. There was no significant difference in mean triglyceride levels either within each group over time or between groups at each testing interval.

Abnormal glucose tolerance test status (impaired glucose tolerance or diabetes mellitus) was not associated with a higher mean cholesterol, low density lipoprotein cholesterol, triglyceride, or with a decreased mean high-density lipoprotein cholesterol level at any testing interval. The study population was overweight (mean body mass index, 29 ± 5). There was no significant weight change from entry during the study period in any of the groups. Although there was a trend toward increasing mean body mass index in patients with impaired glucose tolerance and diabetes mellitus at all testing intervals, these associations were not significant.

Comment

In this study population low-dose oral contraceptives did not influence the development of diabetes mellitus in women with recent gestational diabetes mellitus. These patients were overweight and primarily of Latin American descent or origin. Both these factors are associated with glucose intolerance.[24] Gestational diabetes mellitus class has a major influence on the development of subsequent diabetes. In this study only 7% of patients with class A_1 diabetes were seen to have diabetes mellitus compared with 29% of patients with class A_2 diabetes. The deterioration in glucose tolerance was closely related to the inherent disease process of gestational diabetes mellitus, rather than use of oral contraceptives.

Elevation of lipids during pregnancy is well documented.[25, 26] A delay in the return to normal levels longer than 6 weeks post partum has been reported.[27] The improvement of lipid profiles by 3 months in all of our study groups suggests a similar gradual return of lipid metabolism to a nonpregnant state in women with prior gestational diabetes mellitus. The mean cholesterol and low density lipoprotein cholesterol levels at 6 to 13 months in these study patients are comparable with those in the Department of Health and Human Services 1978-1980 survey for a similar age cohort of women (25 to 34 years old) in which the mean cholesterol and low density lipoprotein cholesterol levels were 192 ± 34 and 121 ± 33 mg/dl, respectively.[28, 29] The increase after 6 to 13 months of ethinyl estradiol–norethindrone use in high-density lipoprotein cholesterol is likely related to its estrogen-dominant oral contraceptive formulation.

Short-term use of low-dose oral contraceptives in women with prior gestational diabetes mellitus does not appear to have any adverse effect on carbohydrate or lipid metabolism. Both oral contraceptive groups and the non-oral-contraceptive group show a significant and similar deterioration in glucose tolerance with an overall prevalence of 14% impaired glucose tolerance and 17% diabetes mellitus after 6 to 13 months. Low-dose oral contraceptives can be safely prescribed in women with prior gestational diabetes mellitus. Serum lipids and glucose tolerance should be monitored closely regardless of contraceptive choice. The ability to offer these patients an effective, acceptable, and reversible birth control method such as the low-dose OC increases the ability to prevent or plan pregnancies in

accordance with optimal maternal glycemic status and desires. More studies are needed to determine the long-term effect of low-dose oral contraceptive use as well as the natural history of disease progression in patients with gestational diabetes.

We thank the staff and practitioners of Women's Hospital Family Planning Clinic for their dedication and help in caring for these patients and Rebecca Burt, RN, for her assistance as the Diabetes Family Planning Nurse.

Response of placental vasculature to high glucose levels in the isolated human placental cotyledon

Jonathan B. Roth, MD, James A. Thorp, MD, Sue M. Palmer, MD, Peter C. Brath, BS, Scott W. Walsh, PhD, and Sharon S. Crandell, MD

Houston, Texas

We report the effect of high glucose infusion on vascular resistance in isolated human placental cotyledons perfused with Krebs-Ringer–bicarbonate solution containing 80 mg/dl (4.4 mmol/L), 160 mg/dl (8.8 mmol/L), or 320 mg/dl (17.6 mmol/L) D-glucose (n = 6). Placental vascular resistance remained constant during 25-minute perfusion periods with 80 mg/dl followed by 160 mg/dl glucose solution. Subsequent perfusion with 320 mg/dl glucose produced a significant increase in placental vascular resistance. Placentas were also studied in which the placental cotyledon was sequentially perfused for 25-minute periods with solutions containing glucose at 80 mg/dl followed immediately by 320 mg/dl (n = 5). Placental vascular resistance remained constant throughout perfusion with 80 mg/dl glucose solution but increased significantly after beginning perfusion with 320 mg/dl glucose. We conclude that the increase in placental vascular resistance appears to be a function of the high glucose level rather than the duration of glucose perfusion. (AM J OBSTET GYNECOL 1990;163:1828-30.)

Key words: Placenta, glucose, vascular resistance, diabetes

Maternal hyperglycemia results in fetal hyperglycemia, fetal hyperinsulinemia, and an increased flux of glucose into the fetal circulation. These metabolic alterations appear to have a deleterious effect on fetal well-being. Phillips et al.[1] showed that fetal hyperglycemia produced by glucose infusion into the ovine fetus resulted in increased oxygen consumption, hypoxemia, acidemia, and fetal death in fetuses that became severely acidemic. In studying the effects of maternal hyperglycemia on the fetus, we previously showed that the hyperglycemic fetus became hypoxemic and a mixed metabolic respiratory acidemia developed.[2] In addition, umbilical blood flow was significantly decreased at maternal glucose concentrations that were two to three times the normal range for pregnant ewes. The cause of this observed decrease in umbilical blood flow during maternal-fetal hyperglycemia was unclear.

Fetal hypoxemia is a potent stimulus for the release of vasoactive substances that may contribute to reduced placental blood flow. Rankin and Phernetton[3, 4] reported that norepinephrine and prostaglandin E_2 caused vasoconstriction in the placental vascular bed and thereby decreased umbilical blood flow.[4] Angiotensin II increases placental vascular resistance.[5] It is not clear by what mechanism the decrease in umbilical blood flow is initiated or sustained during maternal-fetal hyperglycemia, or what if any role fetal hypoxemia plays in the redistribution of fetal cardiac output and whether this redistribution is mediated by the release of vasoactive agents. Despite extensive in vivo work in glucose metabolism in chronically catheterized ovine fetuses, few investigators have examined directly the effect of glucose on placental vascular resistance. The following in vitro study was undertaken to examine the effects of high glucose levels on vascular resistance in the human placenta.

Material and methods

The method used involved simultaneous in vitro perfusion of the placental vasculature and the intervillous space in the isolated human placental cotyledon as previously described by Schneider et al.[6] and Thorp et al.[7] The placentas were obtained immediately after vaginal or cesarean section delivery and placed into a bath of physiologic saline solution at room temperature. An intact lobe on the fetal side of the placenta suitable for dual perfusion was selected and the arterial and venous chorionic vessels supplying that lobe were catheterized. The placenta was then secured onto a chamber and two butterfly needles were pierced through the decidual

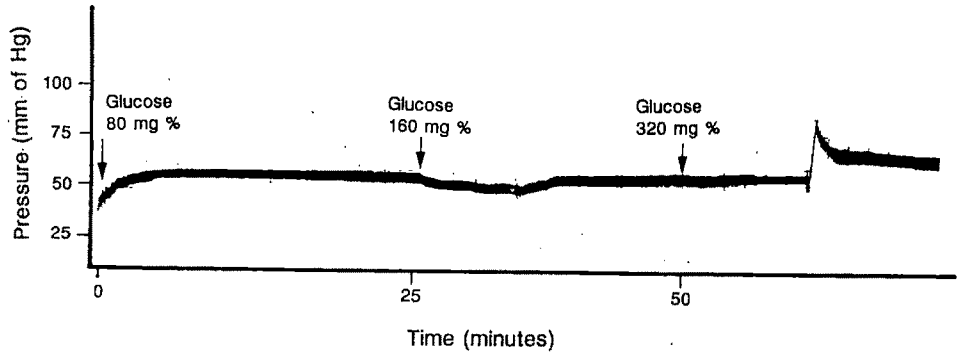

Fig. 1. Representative tracing of change in pressure of chorionic plate artery during perfusion of isolated human placental cotyledon with sequentially increasing concentrations of glucose (80 mg/dl (4.4 mmol/L), 160 mg/dl (8.8 mmol/L), and 320 mg/dl (17.6 mmol/L).

plate of the maternal side of the placenta. The fetal flow was set at 2 to 5 ml/min and the maternal flow at 7 to 12 ml/min. The maternal and fetal sides of the placenta were perfused with a Krebs-Ringer–phosphate–bicarbonate solution gased with 95% air and 5% carbon dioxide at 37° C. Pressure changes in the chorionic plate placental arteries and veins were monitored with a physiologic recorder (model 7754B, Hewlett Packard, Waltham, Mass.). Changes in resistance were calculated by dividing the difference between arterial and venous pressures by the measured flow rates.

We studied six placentas (group A). The placental cotyledons were sequentially perfused for 25-minute periods with solutions that contained glucose of 80 mg/dl (4.4 mmol/L), 160 mg/dl (8.8 mmol/L), and 320 mg/dl (17.6 mmol/L). In addition, five placentas were studied in which the placental cotyledons were sequentially perfused for 25-minute periods with solutions that contained glucose at 80 mg/dl (4.4 mmol/L) followed by 320 mg/dl (17.6 mmol/L) (group B). Solutions of mannitol of 80 mg/dl (4.4 mmol/L), 160 mg/dl (8.8 mmol/L), and 320 mg/dl (17.6 mmol/L) were used to perfuse two additional placentas. Data were analyzed as appropriate by the paired Student *t* test or analysis of variance with random block due to variability between placentas. Tissue viability was determined in six placentas by measuring lactate production after 15 minutes, 60 minutes, and 120 minutes of perfusion.

Results

There was no significant change in lactate production throughout the experiment, indicating that the tissue remained viable during experimental procedures. Mean lactate production at 15 minutes was 0.79, at 60 minutes 0.89, and at 120 minutes 0.97 mmol/min/gm. These values are within the range reported by others.[8] Placental vascular resistance remained constant throughout a 25-minute perfusion with 80 mg/dl glucose solution and throughout a 25-minute perfusion with 160 mg/dl glucose solution. Within 12 ± 3 minutes of beginning the perfusion with 320 mg/dl glucose, a significant increase of 110% ($p < 0.05$) in placental vascular resistance was observed (Fig. 1, Table I).

Table I. Placental vascular resistance in response to perfusion with different concentrations of glucose studied in the isolated human placental cotyledon

	Resistance (mm Hg · min/ml)	
Glucose (mg/dl)	*Group A mean ± SE (n = 6)*	*Group B mean ± SE (n = 5)*
80	14.17 ± 4.26	16.82 ± 3.56
160	14.26 ± 4.22	—
320	30.00 ± 11.4	31.49 ± 5.25

In an additional five placentas studied, vascular resistance remained constant throughout a 25-minute perfusion with 80 mg/dl glucose solution. Within 11 ± 3 minutes of beginning the perfusion with 320 mg/dl glucose, a significant increase of 87% in placental vascular resistance was observed ($p < 0.01$) (Fig. 2, Table I). In the two placentas perfused with mannitol, vascular resistance remained constant throughout sequential perfusions with mannitol solutions of 80 mg/dl, 160 mg/dl, and 320 mg/dl, which shows that the vasoconstriction observed with 320 mg/dl glucose was not simply an osmotic effect.

Comment

Placental vascular resistance increased in response to high glucose levels. The absence of a response in the placentas perfused with mannitol indicates that this re-

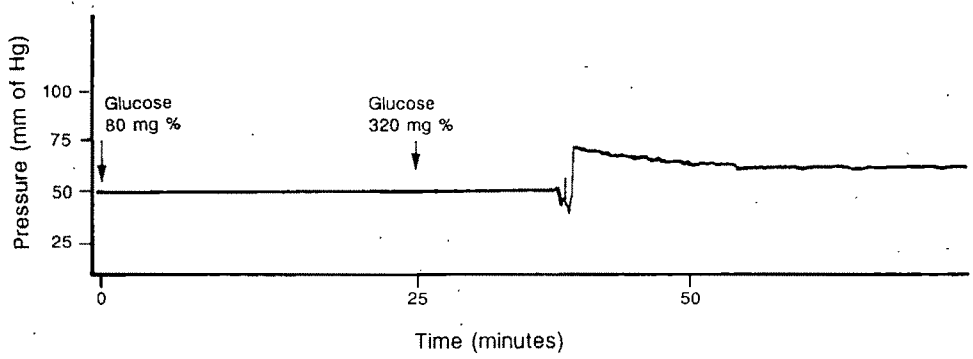

Fig. 2. Same as Fig. 1, except the 320 mg/dl glucose perfusion immediately followed the 80 mg/dl glucose perfusion.

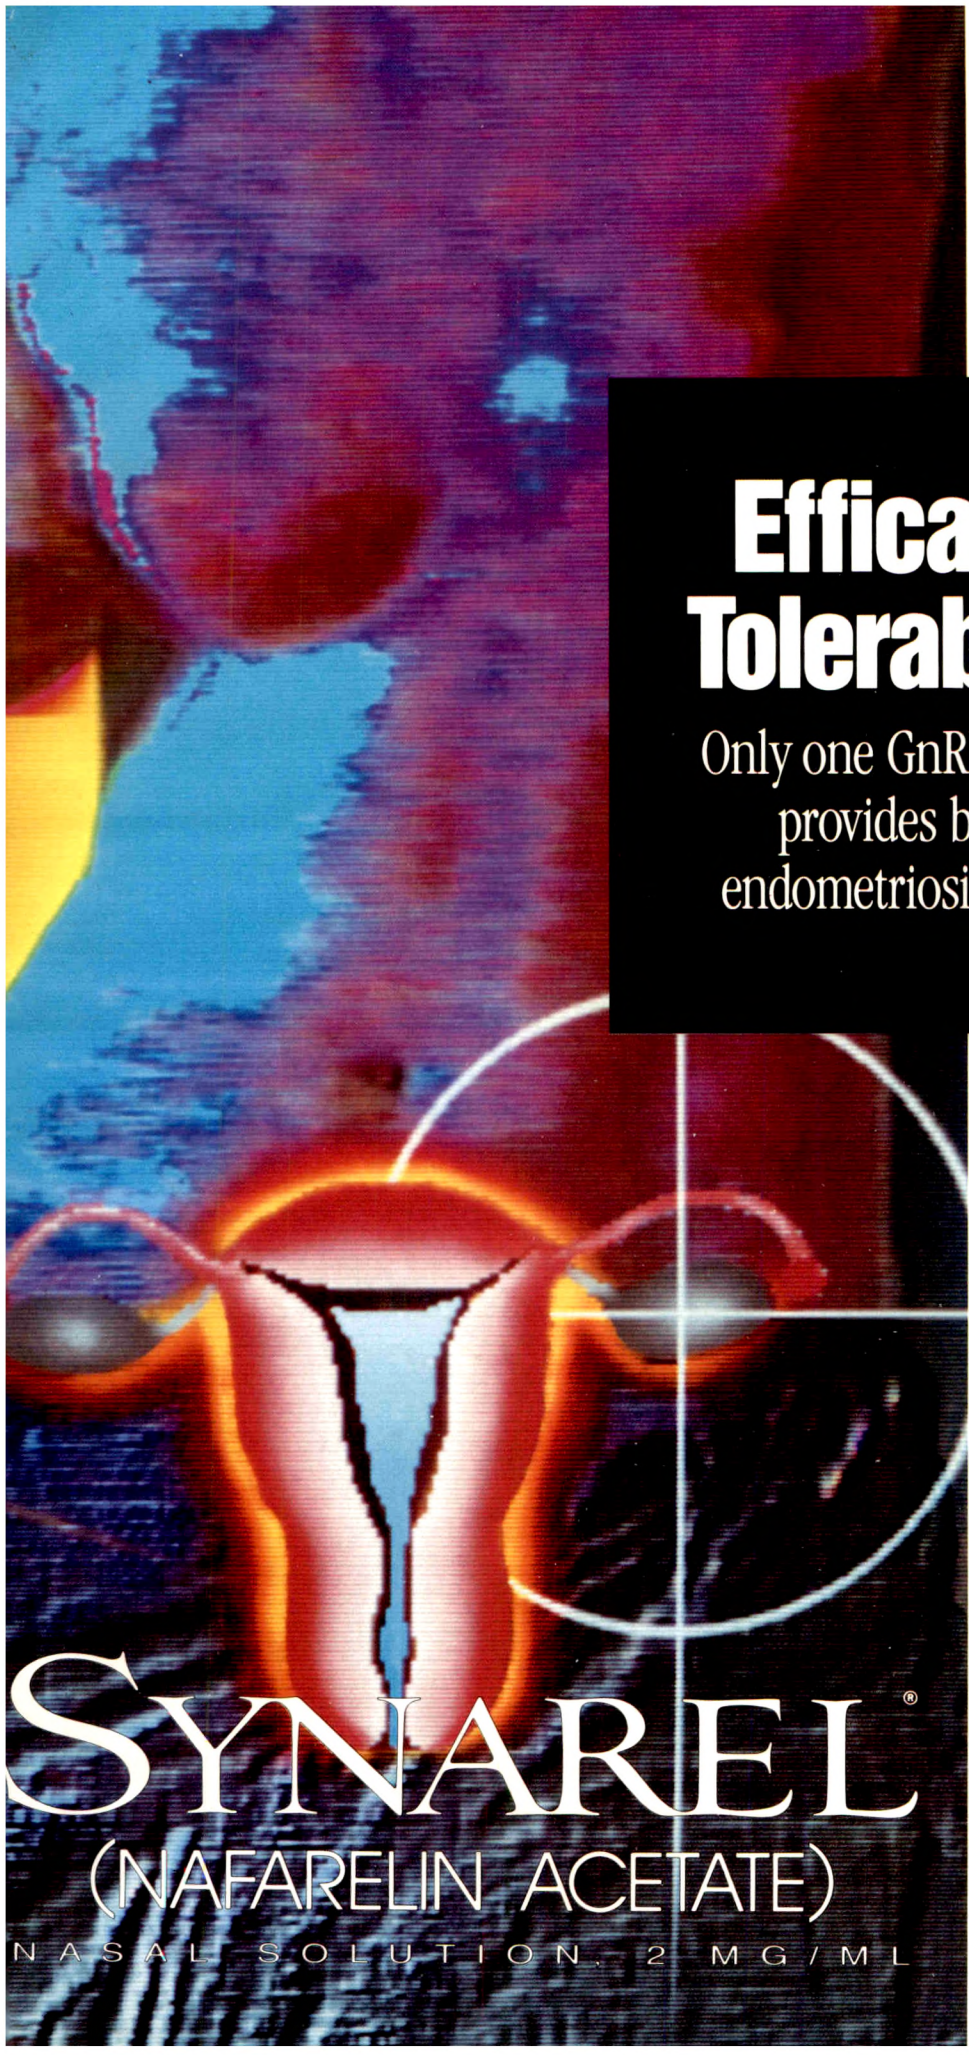

sponse is not an osmotic effect. In addition, the increase in placental vascular resistance appears to be a function of the high glucose level and not a result of a time-related effect of the glucose perfusion. Because there are differences in the anatomic relationship of the perfusing vessels in the sheep versus the human placenta, one cannot be certain that high glucose levels would produce similar vasoconstriction in the sheep placenta. The data do, however, suggest that the decrease in umbilical blood flow observed by Crandell et al.[2] in the intact pregnant sheep may have resulted from changes in resistance in the placental vascular bed as a consequence of maternal hyperglycemia.

The mechanism for the increase in placental vascular resistance after perfusion with high glucose levels is not known. In vivo, fetal hyperglycemia causes hypoxemia. Fetal hypoxemia is a potent stimulus for the release of vasoactive substances that may contribute to increased placental vascular resistance. Fetal hypoxemia evokes the release of vasoconstrictors such as vasopressin, renin, epinephrine, norepinephrine, and prostaglandin E_2 and $F_{2\alpha}$ into the circulation.[3,4,5,9,10] However, this cannot explain vasoconstriction in response to high glucose levels in vitro. High glucose levels caused a decrease in prostacyclin production by cultured trophoblast cells obtained from early pregnancy,[11] and there is a significant decrease in prostacyclin production with no significant change in thromboxane production by placentas obtained from women with diabetes as compared with nondiabetic women.[12] Therefore, vasoconstriction in response to high glucose levels may be related to decreased prostacyclin production leading to an imbalance between thromboxane and prostacyclin levels that favors the vasoconstrictive effects of thromboxane.

We speculate that the increase in placental vascular resistance observed in vitro may explain in vivo the decrease in umbilical blood flow during maternal-fetal hyperglycemia observed in our laboratory in the sheep and by Trudinger et al.[13] in the human uncontrolled diabetic patient.

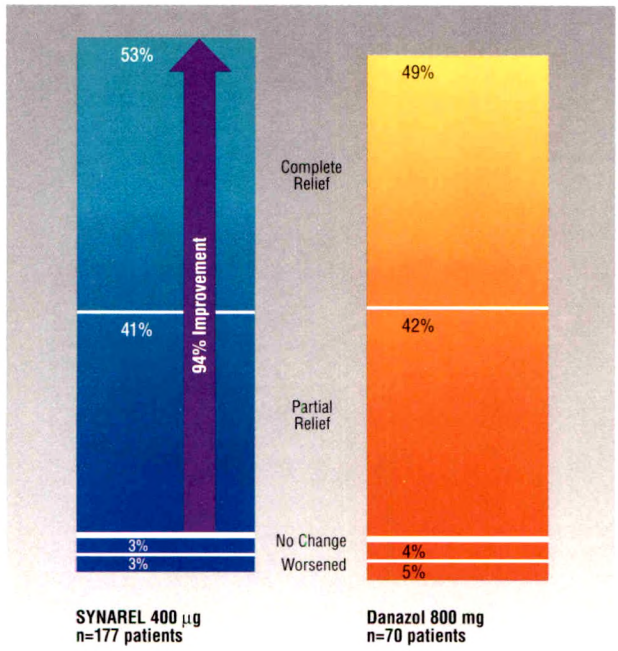
Efficacy & Tolerability:

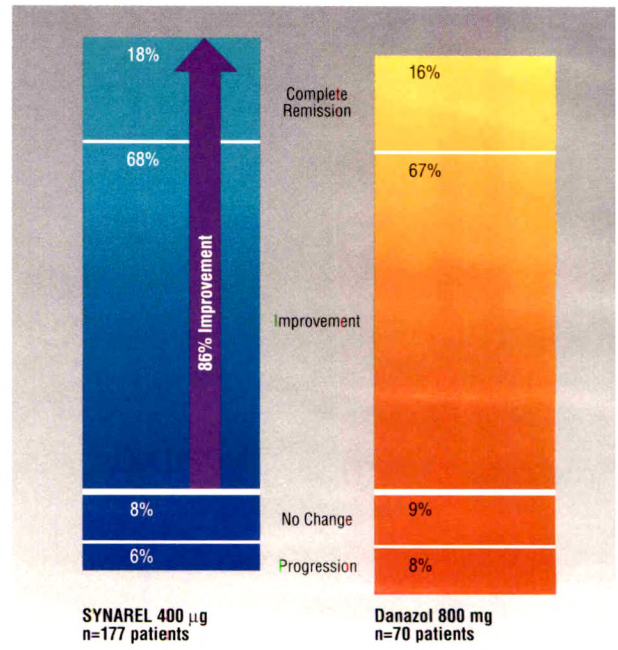
Only one GnRH* agonist provides both in endometriosis therapy

SYNAREL®



(NAFARELIN ACETATE)

NASAL SOLUTION, 2 MG/ML



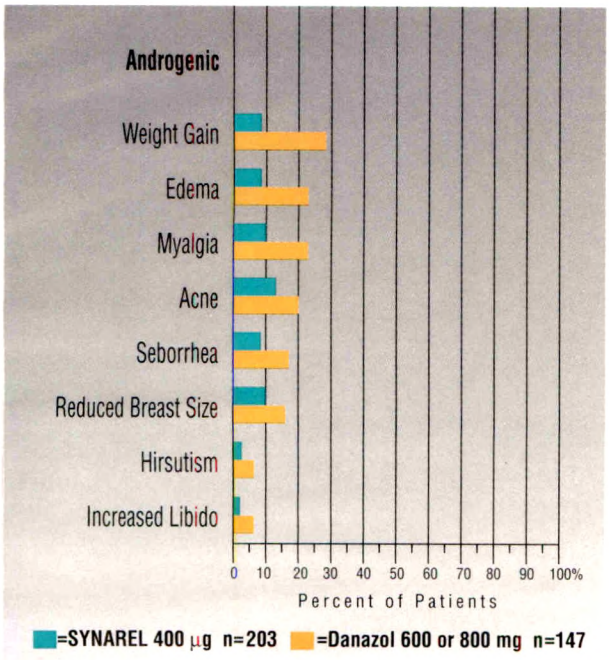
*Gonadotropin-releasing hormone analog
Please see brief summary of prescribing information on last page.

The Only GnRH* Agonist That Satisfies The Needs Of Endometriosis Therapy

Unsurpassed Resolution Of Pain And Endometriotic Lesions

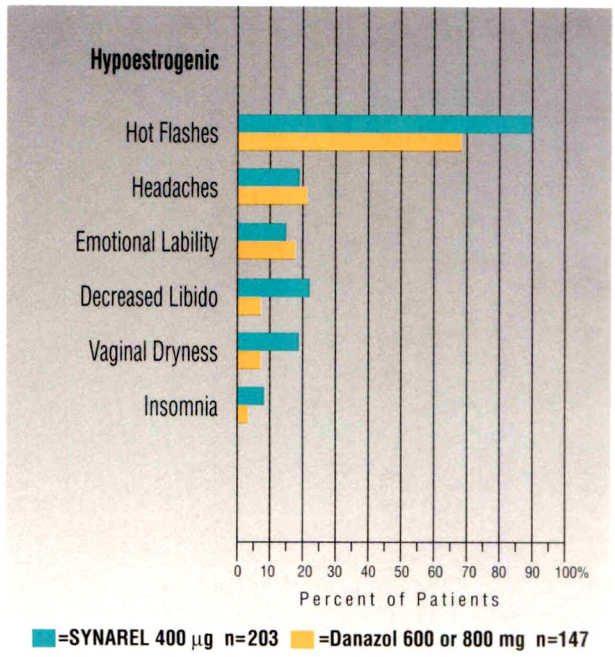
Change in symptom severity scores from admission to end of study

Change in laparoscopy scores from admission to end of therapy



94% of Synarel patients reported improvement of symptoms

- Proven to relieve dysmenorrhea, dyspareunia, and pelvic pain
- Efficacy sustained in 83% of patients at six months posttreatment



86% of Synarel patients showed improvement of endometriotic lesions

- Improvement in all stages of endometriosis confirmed by post-laparoscopy scores†
- Retreatment cannot be recommended since safety data for retreatment are not currently available

Well-Tolerated Management Of Endometriosis, An Estrogen-Dependent Disease

Adverse androgenic effects during six months of treatment

Adverse hypoestrogenic effects during six months of treatment

- Fewer masculinizing side effects than danazol
- Some androgenic effects of danazol, such as deepening of the voice, may be irreversible[1]
- Unlike danazol, NO increase in LDL/HDL ratio after six months of treatment[2]

- A predictable hypoestrogenic profile: Estrogen levels return to normal after cessation of therapy
- Pregnancy should be ruled out before therapy with SYNAREL is initiated. Patients should be advised to use a nonhormonal method of contraception when taking SYNAREL.

SYNAREL®

(NAFARELIN ACETATE)

NASAL SOLUTION, 2 MG/ML

Endometriosis therapy breakthrough

Please see brief summary of prescribing information on last page.

Gonadotropin-releasing hormone analog

Based on American Fertility Society laparoscopy score stages: (absent, score 0); I (minimal, 1–5); II (mild, 6–15); III moderate, 16–40); IV (severe, 40+).

The Only GnRH* Agonist Indicated For The Management Of Endometriosis

- Unsurpassed resolution of pain and endometriotic lesions
- Well-tolerated management of this estrogen-dependent disease
- Fewer masculinizing side effects than danazol (The most frequent side effects are those associated with hypoestrogenism.)
- The only GnRH agonist administered intranasally—assures reliable dosing control

SYNAREL®
(NAFARELIN ACETATE)
NASAL SOLUTION, 2 MG/ML

Endometriosis therapy breakthrough

BRIEF SUMMARY

SYNAREL® Nasal Solution contains nafarelin acetate (2 mg/mL, expressed as nafarelin base), benzalkonium chloric glacial acetic acid, sodium hydroxide or hydrochloric acid, sorbitol, and purified water.

INDICATIONS AND USAGE: For management of endometriosis. Experience is limited to women 18 years and old treated for 6 months.

CONTRAINDICATIONS: Hypersensitivity to GnRH, GnRH agonist analogs or any excipients in SYNAREL; undia nosed abnormal vaginal bleeding; pregnancy or possibility of pregnancy while taking the drug because SYNAREL ma cause fetal harm when administered to a pregnant woman. If SYNAREL is used during pregnancy or if the patie becomes pregnant while taking this drug, she should be apprised of the potential hazard to the fetus; use in women wh are breast feeding.

WARNINGS: Safe use in pregnancy has not been established clinically. Before starting treatment pre nancy must be excluded.

When used regularly at the recommended dose, SYNAREL usually inhibits ovulation and stops menstruation. Cont ception is not insured, particularly if patients miss successive doses. Therefore, patients should use nonhormonal cc traception. Advise patients to see their physician if they believe they may be pregnant. If a patient becomes pregna during treatment, discontinue the drug; apprise patient of the potential risk to the fetus.

PRECAUTIONS Information for Patients: 1. Since menstruation should stop with SYNAREL, the patient shou notify her physician if regular menstruation persists. Patients missing successive doses may experience breakthrouc bleeding.

2. Patients should not use SYNAREL if pregnant, breast feeding, have undiagnosed abnormal vaginal bleeding, or a allergic to any of its ingredients.

3. Safe use in pregnancy has not been established. Therefore, a nonhormonal method of contraception should b used during treatment. If a patient becomes pregnant during treatment, she should discontinue the drug and consu her physician.

4. Adverse events occurring most frequently in clinical studies are associated with hypoestrogenism. Nasal irritatic occurred in about 10% of patients.

5. Induced hypoestrogenic state results in a small loss in bone density over a 6-month treatment course. Some of th loss may not be reversible. During one six-month treatment period, this should not be important. In patients with maj risk factors for decreased bone mineral content, i.e., chronic alcohol and/or tobacco use, strong family history osteoporosis, or chronic use of drugs that can reduce bone mass such as anticonvulsants or corticosteroids, SYNARE may pose additional risk. In these patients risks and benefits must be weighed carefully. Repeated courses of treatme with GnRH analogs are not advisable in patients with major risk factors for loss of bone mineral content.

6. Patients with intercurrent rhinitis should consult their physician for use of a topical nasal decongestant. If a topic nasal decongestant is required during treatment, it must be used at least 30 minutes after SYNAREL dosing to decrea the possibility of reducing drug absorption.

7. Retreatment cannot be recommended since safety data beyond 6 months are not available.

Drug Interactions: No pharmacokinetic-based drug-drug interaction studies have been conducted. Nafarelin aceta is a peptide primarily degraded by peptidase and not by cytochrome P-450 enzymes, and is only about 80% bound plasma proteins at 4°C, therefore drug interactions would not be expected to occur.

Drug/Laboratory Test Interactions: SYNAREL in therapeutic doses suppresses the pituitary-gonadal system. N mal function is usually restored 4–8 weeks after treatment is discontinued. Therefore, diagnostic tests of pituita gonadotropic and gonadal functions during treatment and up to 4–8 weeks after discontinuation of SYNAREL may l misleading.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Carcinogenicity studies were conducted in rats a mice at intramuscular doses up to 110 times and 560 times the maximum recommended human intranasal do respectively. These multiples of the human dose are based on the relative bioavailability of the drug by the two routes administration. As with other GnRH agonists, nafarelin acetate given to laboratory rodents at high doses for prolong periods induced hyperplasia and/or neoplasia of endocrine organs. At 24 months, there was an increase in the inciden of pituitary tumors (adenoma/carcinoma) in high-dose female rats and a dose-related increase in male rats. There w an increase in pancreatic islet cell adenomas in both sexes, and in benign testicular and ovarian tumors in the treat groups. There was a dose-related increase in benign adrenal medullary tumors in treated female rats. In mice, there w a dose-related increase in Harderian gland tumors in males and an increase in pituitary adenomas in high-dose femal No metastases of these tumors were observed. It is known that tumorigenicity in rodents is particularly sensitive hormonal stimulation.

Mutagenicity studies using bacterial, yeast, and mammalian systems provided no evidence of mutagenic potent

Reproduction studies in male and female rats have shown full reversibility of fertility suppression when treatment w discontinued after continuous administration for up to 6 months.

Pregnancy, Teratogenic Effects: *Pregnancy Category X.* Intramuscular SYNAREL was administered to ra throughout gestation at about 0.5, 2, and 7 times the maximum recommended human intranasal dose based on t relative bioavailability by the two routes of administration. An increase in major fetal abnormalities was seen in 4/ fetuses at the highest dose. A similar study at the same doses in rats and studies in mice and rabbits at doses up to 6 μg/kg/day and 0.18 μg/kg/day, respectively, failed to demonstrate an increase in fetal abnormalities after administrati throughout gestation. In rats and rabbits, there was a dose-related increase in fetal mortality and a decrease in fe weight with the highest dose.

Nursing Mothers: It is not known whether SYNAREL is excreted in human milk. Because many drugs are excreted human milk, and because the effects of SYNAREL on lactation and/or the breastfed child have not been determin SYNAREL should not be used by nursing mothers.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: The most frequently reported adverse reactions were those related to hypoestrogenism. controlled studies comparing SYNAREL (400 μg/day) and danazol (600 or 800 mg/day), the following adverse re tions were most frequently reported and thought to be drug-related.

Hypoestrogenic: hot flashes (SYNAREL 90%, danazol 69%), decreased libido (22%, 7%), vaginal dryness (19 7%), headaches (19%, 21%), emotional lability (15%, 18%), insomnia (8%, 4%); **Androgenic:** acne (13%, 20 myalgia (10%, 23%), reduced breast size (10%, 16%), edema (8%, 23%), seborrhea (8%, 17%), weight gain (8 28%), hirsutism (2%, 6%), increased libido (1%, 6%); **Local:** nasal irritation (10%, 3%); **Miscellaneous:** depressi (2%, 5%), weight loss (1%, 3%).

Less than 1% of patients experienced paresthesia, palpitations, chloasma, maculopapular rash, eye pain, urtica asthenia, lactation, breast engorgement, and arthralgia. In clinical trials, immediate hypersensitivity thought to be p sibly or probably related to nafarelin occurred in 3 (0.2%) of 1509 healthy subjects or patients.

Changes in Bone Density: After 6 months' treatment vertebral trabecular bone density and total vertebral bone ma measured by quantitative computed tomography (QCT), decreased by an average of 8.7% and 4.3%, respectively, co pared to pretreatment levels. There was partial recovery of bone density post-treatment; the average trabecular bo density and total bone mass were 4.9% and 3.3% less than pretreatment levels, respectively. Total vertebral bone ma measured by dual photon absorptiometry (DPA), decreased by a mean of 5.9% at end of treatment. Mean total verteb mass, re-examined by DPA 6 months post-treatment, was 1.4% below pretreatment levels. There was little, if a decrease in the mineral content in compact bone of the distal radius and second metacarpal. Use for longer than t recommended 6 months or in presence of other known risk factors for decreased bone mineral content may cause ac tional bone loss.

Changes in Laboratory Values: *Plasma enzymes.* During clinical trials SGOT and SGPT levels were more than twi the upper limit of normal in only one patient each. There was no other evidence of abnormal liver function and leve returned to normal after treatment was stopped.

Lipids. At enrollment and at end of treatment, 9% of patients on SYNAREL 400 μg/day and 2% on danazol had to cholesterol values above 250 mg/dL.

Of those with pretreatment cholesterol values below 250 mg/dL, 6% on SYNAREL and 18% on danazol had pc treatment values above 250 mg/dL.

Mean (±SEM) pretreatment values for total cholesterol from all patients were 191.8 (4.3) mg/dL in the SYNARE group and 193.1 (4.6) mg/dL in the danazol group. At the end of treatment, mean values from all patients were 204.5 (4. mg/dL in the SYNAREL group and 207.7 (5.1) mg/dL in the danazol group. These increases from pretreatment valu were significant ($p < 0.05$) in both groups.

Triglycerides were increased above the upper limit of 150 mg/dL in 12% of the patients on SYNAREL and in 7% of t patients on danazol.

At the end of treatment, no patients on SYNAREL had abnormally low HDL cholesterol fractions (< 30 mg/dL) co pared with 43% of patients on danazol. No patients on SYNAREL had abnormally high LDL cholesterol fractio (> 190 mg/dL) compared with 15% of those on danazol. There was no increase in the LDL/HDL ratio in patients SYNAREL, but approximately a 2-fold increase in the LDL/HDL ratio in patients on danazol.

Other changes. In comparative studies, the following changes were seen in approximately 10% to 15% of patien SYNAREL was associated with elevations of plasma phosphorous and eosinophil counts, and decreases in seru calcium and WBC counts. Danazol therapy was associated with an increase of hematocrit and WBC.

OVERDOSAGE: At present there is no clinical evidence of adverse effects following overdosage of GnRH analog

Placental thromboxane and prostacyclin production in an ovine diabetic model

Jan E. Dickinson, MD, Bruce A. Meyer, MD, Peter C. Brath, BS, Susie Chmielowiec, MS, Scott W. Walsh, PhD, Valerie M. Parisi, MD, MPH, and Sue M. Palmer, MD

Houston, Texas

We hypothesized that streptozocin-induced ovine diabetes would cause alterations in the placental production of thromboxane and prostacyclin. With a tissue incubation technique, we examined the placental production of thromboxane and prostacyclin in cotyledons from seven normal near-term ewes (127 ± 3 days' gestation) and six streptozocin-induced diabetic ewes (125 ± 3 days' gestation). Diabetic status was verified with serial fasting blood glucose assessments. Placental tissue was incubated in Dulbecco's modified Eagle's medium for 48 hours at 37° C with 95% oxygen and 5% carbon dioxide. Samples were collected at 0, 1, 2, 4, 8, 20, 32, and 48 hours. Radioimmunoassay of the stable metabolites thromboxane B_2 and 6-keto-prostaglandin $F_{1\alpha}$ were used to determine thromboxane and prostacyclin production, respectively. Placental thromboxane production was reduced in diabetic animals when compared with control animals (5.63 ± 2.81 vs 7.32 ± 1.37 pg/mg per hour, respectively; $p < 0.05$). Prostacyclin production was also significantly reduced in the diabetic placentas compared with control placentas (11.44 ± 4.06 vs 16.29 ± 4.59 pg/mg per hour, respectively; $p < 0.05$). We conclude that the ovine placenta produces thromboxane and prostacyclin. The ovine thromboxane production rate is comparable to that of the human placenta but the prostacyclin production rate is approximately two to three times higher. The observed decrease in the placental production of thromboxane and prostacyclin may reflect an adverse effect of hyperglycemia directly on eicosanoid production or indirectly through decreased placental cellular proliferation. (Am J Obstet Gynecol 1990;163:1831-5.)

Key words: Prostacyclin, thromboxane, placenta, diabetes, ovine

During normal human pregnancy, the placenta produces approximately equal amounts of the vasoactive eicosanoids thromboxane and prostacyclin.[1, 2] Certain disease states are associated with alterations in the placental production of thromboxane and prostacyclin. Diabetes mellitus is a disease characterized by alterations in vascular physiology and eicosanoid production. Previous investigators showed reduced prostacyclin production from the endothelium of large blood vessels in nonpregnant diabetic subjects,[3, 4] and increased platelet thromboxane production.[5] These alterations in the production of eicosanoids appear to be glucose-related. Rakoczi et al.[6] showed a dose-dependent reduction of prostacyclin production in cultured trophoblast cells incubated with increasing glucose concentrations. Prostacyclin synthesis is reduced in the umbilical arteries of neonates of mothers with gestational diabetes mellitus and juvenile-onset diabetes.[7] Maternal gestational diabetes mellitus is associated with a decrease in the in vitro placental production rate of prostacyclin, but not that of thromboxane (Palmer SM, Young S, Walsh SW. Unpublished observations). The clinical implication of reduced placental prostacyclin production in gestational diabetes may be decreased placental blood flow, limited vasodilation, and increased platelet aggregation. These alterations in placental physiology may impact on the capacity of the fetus of the diabetic mother to respond to changes in uteroplacental perfusion.

Preeclampsia is a common complication of pregnancy in the diabetic patient, particularly in women with poor glucose control. In preeclampsia the placental production of the vasoconstrictor thromboxane is seven times that of the vasodilator prostacyclin, and this imbalance has been postulated to account for some of the pathophysiology of this disease.[1, 2] The frequency with which diabetes and preeclampsia are associated in pregnancy prompted our investigation of the placental production of eicosanoids in diabetes.

With the pregnant ewe, we investigated the role of the vasoactive eicosanoids in normal and diabetic pregnancies. We hypothesized that the ovine placenta produces thromboxane and prostacyclin, and that streptozocin-induced diabetes mellitus would alter the production rates of these eicosanoids.

Material and methods

Six pregnant ewes of known gestational age were rendered glucose intolerant by the intravenous administration of streptozocin (Upjohn Co., Kalamazoo, Mich.) on two separate occasions, 4 days apart, commencing at 85 to 95 days' gestation. Before each injection of streptozocin, a 3-hour intravenous glucose tolerance test with 25 gm of glucose administered as 50 ml of 50% dextrose in water was conducted. At the completion of the glucose tolerance test, streptozocin was administered to the ewe at a dose of 50 mg/kg maternal weight. Immediately before injection, the streptozocin was reconstituted in 50 ml of sterile 0.9% sodium chloride and then infused over 3 to 4 minutes via a maternal peripheral hind-limb vein. To ensure active secretion of insulin and maximal degranulation of the pancreatic β-cells, the streptozocin was injected while the animals were feeding. A third maternal intravenous glucose tolerance test was performed at 114 to 123 days' gestation, 5 days before surgery. Maternal venous plasma fasting blood glucose levels were assessed with a glucose analyzer (model 23A, Yellow Springs Instrument Company, Inc., Yellow Springs, Ohio) before the first administration of streptozocin and again before surgery at 119 to 128 days' gestation.

At 112 to 121 days' gestation the ewes were transferred to the Animal Care Center at our institution and acclimated for a minimum of 7 days before surgery. A diet of pelleted alfalfa and hay was fed to the ewes. The animals were maintained in accordance with the National Institutes of Health Guide for the Care and Use of Laboratory Animals (National Institutes of Health Publication No. 85-23, 1985) in the Animal Care Center of the University of Texas Medical School at Houston. The experimental protocol was approved by our institutional Animal Welfare Committee.

Placental cotyledons, approximately 3 cm in diameter, were obtained at the time of surgery from six glucose-intolerant (125 ± 3 days' gestation) and seven control sheep (127 ± 3 days' gestation). The cotyledon closest to the uterine incision site was selected and atraumatically excised, with double ligation of the vascular pedicle. After harvesting of the placental cotyledons in both glucose-intolerant and control ewes, the insertion of maternal and fetal vascular catheters was performed for the purpose of later experimentation with radioactive microspheres.

Placental tissues were immediately chilled and processed under sterile conditions at 4° C as previously described.[1,2] Placental tissues were separated, gently cut into thin-layer pieces, and washed repeatedly with Dulbecco's modified Eagle's medium (Gibco, Grand Island, N.Y.). Excess modified Eagle's medium was removed with sterile gauze. Multiple wells, each containing approximately 350 mg of placental tissue, were incubated in 7 ml of modified Eagle's medium for 48 hours at 37° C in a Dubnoff metabolic shaker. Tissues were oxygenated with 95% oxygen and 5% carbon dioxide. Samples of media (200 μl) were collected at 0, 1, 2, 4, 8, 20, 32, and 48 hours of incubation. Tissue viability after 0, 20, 32, and 48 hours of incubation was assessed by trypan blue dye exclusion staining as previously described.[2] Results were considered valid if tissue viability was >80%.

The production of thromboxane A_2 was estimated by determination of the concentration of its stable metabolite, thromboxane B_2, with a highly specific radioimmunoassay. The assay consisted of competitive binding of radioactive and natural thromboxane B_2 to a highly specific antibody. Dextran-coated charcoal was used to separate the bound from the free fraction. Cross-reactivity of the antibody with other eicosanoids was <0.1%. Within-assay variation was 5.8% and between-assay variation was 14.0% ($n = 6$). The least detectable concentration was 0.7 ± 0.2 pg, and 50% binding of the standard curve was 16.5 ± 1.3 pg ($n = 6$). Serial sample dilutions were parallel to the standard curve, and the addition of increasing amounts of thromboxane B_2 to modified Eagle's medium resulted in a linear dose response ($r^2 = 1.00$, $y = 1.08x + 0.00$, $n = 6$). A zero dose response resulted from modified Eagle's medium alone. The production of prostacyclin was determined by specific radioimmunoassay of its stable metabolite, 6-keto-prostaglandin $F_{1\alpha}$ (6-keto-$PGF_{1\alpha}$). The radioimmunoassay method and its validation were performed in the same manner to that described for thromboxane.[1] The within-assay variation was 10.9% and between-assay variation was 13.1% ($n = 3$). The least detectable concentration was 0.8 ± 0.2 pg, and 50% binding of the standard curve was 30.1 ± 2.4 pg ($n = 3$). As with thromboxane, the addition of increasing amounts of 6-keto-$PGF_{1\alpha}$ to modified Eagle's medium showed a linear dose response ($r^2 = 0.9993$, $y = 1.10x - 8.5$, $n = 3$). All data are mean ± SE.

Statistical analysis was performed by independent Student's t test (comparison of production rates), simple linear regression (calculation of production rates) and two-way analysis of variance with random block (comparison of the concentration regression lines) with a computer statistical software package (Abstat, Anderson-Bell, Parker, Colo.). Logarithmic transformation [log (x + 1)] was used when variances were not equal. All data are mean ± SE. A probability of $p < 0.05$ was chosen to represent statistical significance.

Results

After streptozocin administration, the fasting venous plasma glucose values of the six ewes rose significantly from a pretreatment level of 71.4 ± 17.0 mg/dl to

121.7 ± 43.0 mg/dl 4 weeks later, $p < 0.05$ (Fig. 1). Maternal venous plasma glucose values have been reported for the normal pregnant ewe and show a gradual decrease as gestation advances. Normoglycemia for the late gestation ewe is 63.8 ± 8.7 mg/dl.[8]

The concentrations of 6-keto-$PGF_{1\alpha}$ and thromboxane B_2 in the incubation media of both the control and diabetic cotyledons increased progressively during the initial 32 hours of incubation. There was a significant fall in tissue viability from 89% at 32 hours to 64% at 48 hours in the diabetic cotyledons ($p < 0.05$). This decline in tissue viability was associated with a decrease in production of thromboxane and prostacyclin between 32 and 48 hours. There was no significant alteration in tissue viability in the diabetic tissue at any other time period (range, 84% to 92%). Tissue viability remained >80% at all the time periods assessed for the control tissue (range, 86% to 92%).

The concentrations of the stable metabolite of thromboxane, B_2, in the incubation medium during 32 hours of incubation of control and diabetic placental tissue are shown in Fig. 2. The concentrations of B_2 are higher at all sampling times for control tissue than for diabetic tissue. Peak levels after 32 hours were 260.7 ± 44.5 pg/mg in the nondiabetic cotyledons and 173.3 ± 80.5 pg/mg in the diabetic placental tissue. The lower half of the figure shows the B_2 production rates for the sampling time intervals of 0 to 1, 1 to 2, 2 to 4, 4 to 8, 8 to 20, and 20 to 32 hours. The production rates are greatest during the first 8 hours of incubation for both control and diabetic tissue. Thereafter, thromboxane production decreased for both groups, but was higher for control tissue than for diabetic tissue at all time intervals. Average production rates during the 32 hours of incubation were determined by calculation of the slopes of the regression lines between each sampling time interval. In comparison with control tissue, the production rate of thromboxane by diabetic placental cotyledons was significantly less. The average production rate for the nondiabetic placental tissue over the 32-hour period was 7.32 ± 1.37 pg/mg per hour ($n = 7$). The average production rate for the diabetic cotyledons was 5.63 ± 2.81 pg/mg per hour ($n = 5$), and was significantly lower than that of nondiabetic cotyledons (t test, $p < 0.05$). The concentration regression line for thromboxane was also significantly lower for the diabetic group than for the control group (two-way analysis of variance, $p < 0.05$). The ovine placental production rate for thromboxane was similar to that reported for normal human placental tissue.[1]

The placental production rates of prostacyclin for control and diabetic animals, as estimated by measurements of 6-keto-$PGF_{1\alpha}$, are shown in Fig. 3. The concentrations of 6-keto-$PGF_{1\alpha}$ in the incubation medium increased progressively during the 32 hours of study.

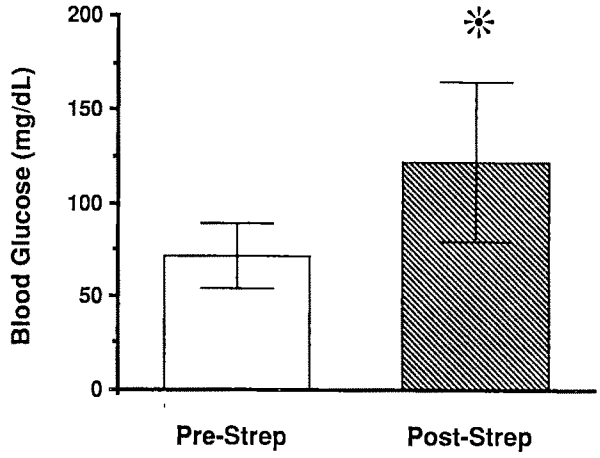

Fig. 1. Maternal fasting venous plasma glucose values before streptozocin and before surgery (71.4 ± 17.0 vs 121.7 ± 43.0 mg/dl, respectively; $n = 6$. Data represent mean ± SE; $^*p < 0.05$).

The concentrations of 6-keto-$PGF_{1\alpha}$ are higher at all sampling times for control tissue than for diabetic tissue. Peak levels after 32 hours were 560.2 ± 147.5 pg/mg for control cotyledonary tissue and 349.3 ± 113.6 pg/mg for diabetic tissue. The lower half of the figure shows the 6-keto-$PGF_{1\alpha}$ production rates for the sampling time intervals of 0 to 1, 1 to 2, 2 to 4, 4 to 8, 8 to 20, and 20 to 32 hours. The production rates are greatest during the first 8 hours of incubation for both control and diabetic tissue. The average production rate over the 32-hour period of incubation was 16.29 ± 4.59 pg/mg per hour ($n = 5$) and 11.44 ± 4.06 pg/mg per hour ($n = 6$) for control and diabetic placental cotyledons, respectively. The production rate of prostacyclin was significantly lower (t test, $p < 0.05$) in diabetic than in control placental tissue. Similarly, the regression line for prostacyclin metabolite concentrations was significantly lower for the diabetic group (two-way analysis of variance, $p < 0.05$). The production rate of prostacyclin in normal ovine cotyledons was approximately two to three times greater than that previously reported for normal human placental tissue in our laboratory.[1,2]

Comment

In this study we used the naturally occurring nitrosourea, streptozocin, to create a large animal model to investigate diabetes in pregnancy. Streptozocin induces destruction of the pancreatic islet cells through an immune-mediated mechanism. In human beings, streptozocin is used therapeutically to treat metastatic pancreatic islet cell carcinoma.[9] This agent has been used previously to induce diabetes in small research laboratory animals such as the rat, dog, and rhesus monkey.[10-12] Spontaneous diabetes mellitus has not been

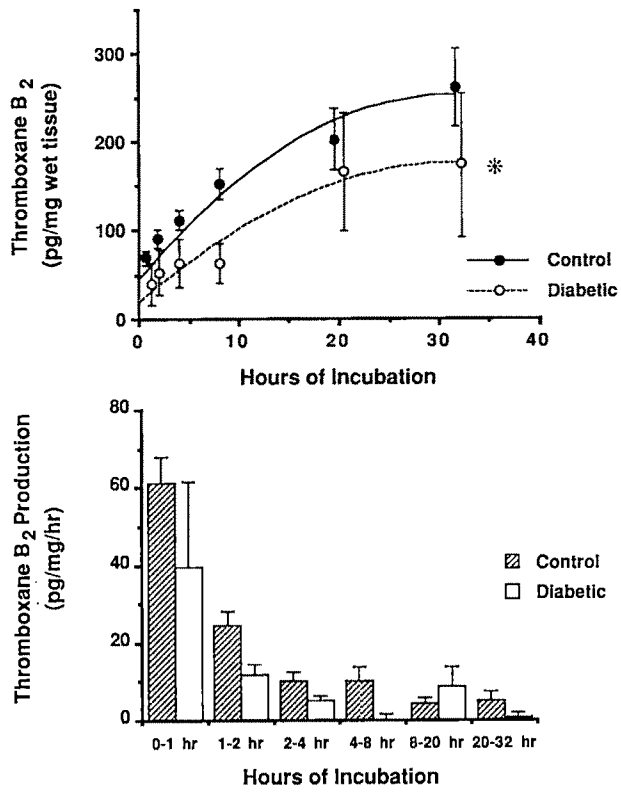

Fig. 2. Production rates of thromboxane by normal and diabetic placental tissues, as estimated by concentrations of its stable metabolite, thromboxane B_2 in incubation medium. Data represent mean ± SE; $*p < 0.05$).

reported in the ovine species and the mean maternal plasma glucose level at late gestation is 63.8 ± 8.7 mg/dl.[8] The observed significant elevation of the fasting plasma glucose level of the streptozocin-treated ewes indicated the induction of a diabetic state. However, the sheep is a ruminant species with little dietary intake of glucose and has a different insulin-glucose response to meals than that of human beings. Our previous work with this animal model showed only small fluctuations in plasma glucose levels (30 to 40 mg/dl) with meals. Thus the mean plasma glucose level is consistently elevated, but unlike the human beings with gestational diabetes, large meal-related glucose fluctuations are not present.

Our study clearly shows that the ovine placenta produces thromboxane and prostacyclin in amounts that approximate human placental production.[1,2] The ovine placenta is epitheliochorial in structure, unlike that of the human being, which is hemochorial in architecture. Despite this fundamental structural difference, the placentas of both species produce the vasoactive eicosanoids thromboxane and prostacyclin at rates that are of a similar order of magnitude, although the ovine placenta produces approximately two to three times more prostacyclin than that of human beings. Our laboratory has previously showed placental thromboxane production rates of 6.3 ± 1.5 pg/mg per hour and placental prostacyclin production rates of 6.7 ± 0.5 pg/mg per hour in normal term human placentas.[1] This results in a ratio of thromboxane to prostacyclin production of 0.94.[2] In contrast, the thromboxane/prostacyclin ratio in the normal near-time ovine placenta is 0.45. This ratio favors the production of prostacyclin. This difference may account in part for the resistance of ovine species to the development of preeclampsia.

In human pregnancy, gestational diabetes is a prominent source of perinatal mortality and morbidity. The effects of the hyperglycemia associated with gestational diabetes on placental function is uncertain. Preliminary investigations in our laboratory with human tissue have suggested a reduction in the placental production rate of the vasodilator prostacyclin in gestational diabetes (Palmer SM, Young S, Walsh SW. Unpublished observations). This reduction was not accompanied by a significant alteration in the placental production rate of the vasoconstrictor thromboxane, so the ratio of thromboxane to prostacyclin favors thromboxane. This is suggestive of a possible mechanism for reduced placental blood flow in gestational diabetes.

We observed a significant reduction in tissue viability and eicosanoid production at 48 hours of incubation

in the ovine diabetic cotyledons. High glucose levels may have directly impaired eicosanoid synthesis or affected viability. Rakoczi et al.[6] showed a dose-dependent inhibition of human placental prostacyclin synthesis by glucose. Another possibility is that hyperglycemia may have decreased cellular proliferation of the placenta. An adverse effect of hyperglycemia on in vitro cellular proliferation of human placental tissue has been reported.[13] A reduction of in vivo cellular proliferation resulting from hyperglycemia is a possible mechanism to account for the reduced in vitro eicosanoid production and impaired tissue viability observed after 48 hours of incubation. Consistent with these findings, we anecdotally noted a decrease in the tissue turgor and quality of the placental cotyledons obtained from the diabetic animals. There was no significant alteration in tissue viability at any other time period. Thus an alteration in tissue viability is not the cause of the observed changes in eicosanoid production.

The placental production of prostacyclin in the diabetic ewe was significantly reduced when compared with the nondiabetic control animals. This is consistent with earlier observations in the human gestational diabetic (Palmer SM, Young S, Walsh SW. Unpublished observations). The placenta of the nondiabetic ewe produced 1.4 times as much prostacyclin as the diabetic placenta. However, unlike human gestational diabetes, we found a significant reduction in thromboxane production in the ovine diabetic placenta. The control ovine placenta produced 1.3 times as much thromboxane as the diabetic placenta. The ovine diabetic placental thromboxane/prostacyclin ratio was 0.49. Thus the thromboxane/prostacyclin ratio in diabetic animals was not altered, despite the reduction in the production rate of these vasoactive eicosanoids ($p > 0.5$).

The reason for the observed differences between the ovine and human placental eicosanoid production rates in gestational diabetes may relate to interspecies variation in placental structure and function. Another potential explanation for the observed differences in production of thromboxane and prostacyclin is a difference in the availability or metabolism of arachidonic acid in the diabetic animals. Alterations in cholesterol metabolism are frequently associated with the alterations of glucose metabolism in diabetes mellitus in human beings. The diet of the ewe is deficient in lipids, potentially resulting in substrate reduction for cyclooxygenase metabolism. It is also possible that the streptozocin directly altered placental function because the agent was administered during pregnancy. It is believed that this compound has a specific affinity for the pancreatic islet cell.[10] However, to be certain that streptozocin has no direct effect on placental function, the agent would need to be administered before conception.

We conclude that the ovine placenta produces thromboxane and prostacyclin. The placental production rates of these eicosanoids in human and ovine placentas are of an equivalent order of magnitude. It is of interest that the ratio of thromboxane/prostacyclin is different between the two species. In human beings approximately equal amounts of thromboxane and prostacyclin are produced, whereas in the sheep prostacyclin is produced at a rate that is over twice that of thromboxane. The epitheliochorial ovine placenta possesses a distinct maternal vascular component, whereas in the human hemochorial placenta there is only a fetal vascular component. Therefore the ovine placenta contains more vascular tissue capable of producing prostacyclin, possibly accounting for the observed differences in production. The presence of maternal hyperglycemia in the ewe is associated with a reduction in the placental production of both thromboxane and prostacyclin, without alteration in the thromboxane/prostacyclin ratio.

We would like to acknowledge Wil Morgan and the Upjohn Company for their assistance in this research.

Insulin-like growth factor II and nonsuppressible insulin-like activity levels in newborns

Naguib A. Samaan, MD, PhD, Pamela N. Schultz, RN, MS, and Frank K. Pham, BS
Houston, Texas

We measured insulin-like growth factor II and nonsuppressible insulin-like activity levels in the sera of newborn infants with different birth weights and gestational ages to determine the significance of these peptides in fetal growth. Our results obtained by use of one-way analysis of variance showed that the insulin-like growth factor II and nonsuppressible insulin-like activity levels in premature, average-weight-for-gestational-age, large-for-gestational-age, and small-for-gestational-age newborns were significantly different ($p < 0.01$). Although levels in the premature neonates were less than the other three groups and large-for-gestational-age neonates had a higher insulin-like growth factor II level than the other three groups, maternal insulin-like growth factor II levels in all groups were similar. These results suggest that insulin-like growth factor II may play a major role in fetal growth. (AM J OBSTET GYNECOL 1990;163:1836-9.)

Key words: Insulin-like growth factor, nonsuppressible insulin-like activity, fetal growth

The mechanism responsible for fetal growth in utero remains to be determined. The description of the sequence of the insulin-like growth factors I and II, which were isolated from the nonsuppressible insulin-like activity by Rinderknecht and Humbel[1] in 1976, resulted in marked progress in this field. The isolation of these growth factors, also known as somatomedins, was preceded by the description of "typical" and "atypical" insulin-like activity by Samaan et al.[2, 3] that was later termed "suppressible" and "nonsuppressible" insulin-like activity by Froesch et al.[4] The serum component (sulfation factor), which mediated the growth hormone-induced incorporation of sulfate into cartilage, was described by Salmon and Daughaday.[5]

In addition to purifying insulin-like growth factors I and II from nonsuppressible insulin-like growth factors, Rinderknecht and Humbel[1] also determined their amino acid sequence, which was found to be similar to proinsulin. Zapf et al.[6] found that both insulin-like growth factors I and II fulfill all the criteria of somatomedins. The origin of somatomedins has been a subject of extensive research. Samaan et al.[7, 8] showed strong evidence that atypical or nonsuppressible insulin-like activity was formed mainly in the liver because they found that the atypical insulin-like activity level was significantly lower in patients with liver cirrhosis and was lowered further after portocaval shunt. They also showed that infusion of regular insulin into the portal circulations of dogs resulted in the increase of the level of the atypical or nonsuppressible insulin-like activity.[9] These observations have been confirmed by various investigators.[6, 10-12] Recently, Daughaday et al.[13] also showed evidence that the liver plays a major part in the formation of sulfation factor when growth hormone was infused in the liver and that insulin has synergetic effect on growth hormone. It was then concluded that growth hormone, insulin, and nutritional factors are most responsible for the formation of the somatomedins.[14]

Underwood et al.[15] purified and separated somatomedin C, which was found to be structurally similar to insulin-like growth factor I and has potent action in cartilage similar to the sulfation factor. Conversely, insulin-like growth factor II was found to be more potent on adipose tissue.[6, 14, 15]

Insulin-like growth factor I has been measured in pregnant mothers and umbilical cords, and it was found that growth hormone and insulin-like growth factor I do not appear related to the growth of the fetus.[14, 16] However, the relationship of insulin-like growth factor II to fetal growth and time of gestation has not been clarified.

This study was undertaken to determine both the insulin-like growth factor II levels, as measured by the radioimmunoassay, and the nonsuppressible insulin-like activity level, as measured by the fat pad assay in the sera of the newborn infants with different birth weights, gestational ages, and 1-minute Apgar scores

so that the significance of these peptides in fetal growth could be determined.

Material and methods

At the time of delivery, sera were collected by venipuncture from 54 women with normal pregnancies at term (37 to 41 weeks) and who were delivered of average-for-gestational-age (AGA) newborns, 53 women who were at term and were delivered of large-for-gestational-age (LGA) infants, five women who were delivered of small-for-gestational-age (SGA) infants, and eight women who were delivered of premature newborns. Categories were based on data provided by Williams et al.[17] in a study conducted in California of 2,288,806 live births. Infants who had reached 37 weeks' gestation and whose weight was ≤10th percentile were considered SGA. Those with weights ≥90th percentile were considered LGA, and those with weights between the 11th and 89th percentiles were considered AGA. An infant was considered premature if the gestational age at birth was ≤36 weeks. The premature newborns in this study had average weights for their gestational age.

Umbilical cord blood was collected from the placental side at the time of delivery immediately after the cord was clamped. The blood was collected in nonheparinized tubes. The serum was separated and kept at −20° C until the time of assay. This study was done with the approval of the Human Protection Committee and informed consent was obtained from each mother.

The insulin-like growth factor II was measured by the radioimmunoassay method after separation of insulin-like growth factor II from the binding proteins by use of the C18 Sep-pak silica cartridge chromatography and a vacuum elution system method. The insulin-like growth factor II was measured by the double-antibody radioimmunoassay method.[18] The first antibody was a monoclonal antibody raised against rat insulin-like growth factor II obtained from Enzyme International (Troy, Va.). It had a 100% crossreactivity with human insulin-like growth factor II and rat insulin-like growth factor II; human insulin-like growth factor I was 10% and bovine insulin was <0.01%. Biosynthetic human insulin-like growth factor II (Eli Lilly & Co., Indianapolis) was used for iodination and assay standards. Interassay variation in insulin-like growth factor II was <20%.

The nonsuppressible insulin-like activity was measured in the serum with the fat pad assay in the presence of glucose carbon 14 isotope and insulin antibody as described by Samaan et al.[3] To make an overall comparison that describes significant differences between groups, a one-way analysis of variance that uses the F test was done to determine the effect of birth weight and gestation on nonsuppressible insulin-like activity and insulin-like growth factor II. Specific differences were analyzed by means of the Tukey test.

Table I. Nonsuppressible insulin-like activity and insulin-like growth factor II levels in premature, SGA, AGA, and LGA newborns

Newborns	*Nonsuppressible insulin-like activity (μU/ml)*	*Insulin-like growth factor II (ng/ml)*
Premature (n = 10)	125 ± 59	48.2 ± 10.9
SGA (n = 4)	211 ± 83	54.0 ± 6.6
AGA (n = 54)	153 ± 121	57.9 ± 11.1
LGA (n = 53)	272 ± 161	63.8 ± 11.4
F test	4.50 ($p < 0.01$)	6.01 ($p < 0.01$)

The one-way analysis of variance that uses the F test was done to determine the effect of birth weight and gestation.

Results

Table I summarizes the mean ± SD of the nonsuppressible insulin-like activity and insulin-like growth factor II levels of the premature neonates, SGA, AGA, and LGA neonates. When analysis of variance was applied to the nonsuppressible insulin-like activity levels, there was a significant difference found among the four groups ($F = 4.50$, $p < 0.01$). The nonsuppressible insulin-like activity levels in the premature neonates was less than in the other three groups, and the nonsuppressible insulin-like activity levels in the LGA group was greater than in the other three groups. The significant differences according to the Tukey test was LGA versus premature ($q = 4.57$, $p < 0.01$) and LGA versus AGA ($q = 4.49$, $p < 0.01$). The insulin-like growth factor II level was similar to the nonsuppressible insulin-like activity in that the insulin-like growth factor II levels of the four groups were significantly different ($F = 6.01$, $p < 0.01$). The insulin-like growth factor II level of the premature neonate was less than the other three groups, and the LGA neonates had higher insulin-like growth factor II levels than in the other three groups. The significant difference according to the Tukey test was LGA versus premature ($q = 5.13$, $p < 0.05$).

The maternal insulin-like growth factor II levels in all patients studied were similar and not significantly different from those found in nonpregnant women of the same age range. The mean ± SD of insulin-like growth factor II levels in the mothers was significantly higher than in all groups of neonates (89.1 ± 5.9, $p < 0.001$). There was no correlation found between maternal weight and their newborn birth weights.

Comment

Little is known about the regulation of somatomedin production in the fetus.[14] It has been shown that

somatomedins do not pass through the placental barrier.[14] The source of the embryonic somatomedins appears to be the fetus itself. Nutritional factors have been proposed to play a primary role in the regulation of somatomedin in the fetus.[14] Both insulin-like growth factor I and II levels are formed in the liver, but to a lesser extent in different tissues including the placenta.[7, 14, 19, 20] It has also been shown that there is a decrease in insulin-like growth factors after experimental manipulation designed to produce growth retardation in the fetal rat.[20, 21]

Brinsmead and Liggins[22] reported that growth hormone is not required for fetal growth because neither somatomedin levels nor growth are affected by hypophysectomy in lambs or decapitation in the uterus. Furthermore, the anencephalic fetuses grow normally during intrauterine life. We and others have also shown that the insulin-like growth factor I level is significantly lower in infants than in adults[16] and was significantly lower in premature newborns than in AGA infants; however, there was no significant difference between the LGA infants and the AGA infants, and we speculated that other growth factors may play a part.

Both insulin-like growth factor I and II levels are found in the circulation with carrier proteins. The exact role of somatomedin-binding proteins in the circulation and how they act to deliver somatomedins to their target tissues is poorly understood. One well-established function is to increase the plasma half-life of somatomedin from 8 to 30 minutes when not protein bound to 3 to 6 hours in the presence of binding proteins.[19] Another apparent role is to provide a reservoir for somatomedin because serum is its primary storage site. It appears that the peptides, when protein bound, exert little of their potential activity. Although this does not necessarily indicate that the naturally occurring high-molecular mass complexes are devoid of activity, evidence exists to suggest that a portion of the total nonsuppressible insulin-like activity level in serum exerts its biologic action when protein bound.[14, 23]

It has also been shown that the binding proteins may interfere with the radioimmunoassay of the somatomedins and acid ethanol extraction was introduced by Daughaday et al.[18] and the use of BioGel P-60 column chromatography appears to be the method of choice since total binding proteins are removed. The combined use of a radioimmunoassay and biologic assay seems to be the best approach for measurements of somatomedins. The fat pad assay appears to measure both insulin-like growth factor I and II levels as well as other related undiscovered peptides.[6]

Our findings indicate that although the insulin-like growth factor II level is low in premature infants, it is also significantly higher in the LGA infants than in the AGA infants. Similar results were obtained by measuring the nonsuppressible insulin-like activity, which is predominantly insulin-like growth factor II.[6, 14] The disparity concerning the rank order of nonsuppressible insulin-like activity levels may be a result of the small number of cases with SGA. The differences in the levels of nonsuppressible insulin-like activity and insulin-like growth factor II in the four categories may reflect a difference in gestational age, birth weight, or both. Thus it appears that insulin-like growth factor II may play a major role in fetal growth.

Growth factor activity in the blood of women in whom preeclampsia develops is elevated from early pregnancy

Robert N. Taylor, MD, PhD,[a] David C. Heilbron, PhD,[b] and James M. Roberts, MD[a]
San Francisco, California

Preeclampsia is a pregnancy-specific disorder of uncertain cause and pathophysiology that appears to be associated with endothelial cell injury. Our current studies demonstrate that a pregnancy growth factor activity is elevated compared with postpartum values in the blood of women with preeclampsia months before the onset of clinical manifestations of toxemia. A cohort of primigravid women was followed throughout pregnancy and multiple serial plasma samples from six women with preeclampsia and six matched normal women were assayed for mitogenic activity. The data indicated that the ratio of predelivery/postdelivery plasma mitogenic activity was greater in women predestined to meet strict criteria for the diagnosis of preeclampsia compared with matched normal primigravid women. Growth factor activity could distinguish women in whom preeclampsia would develop from their normal peers throughout pregnancy, and as early as the first trimester of gestation ($p < 0.05$). Similar studies performed with plasma obtained >6 weeks post partum, when the two groups of patients were clinically indistinguishable, revealed no differences in this index of mitogenic activity. Our results indicate that elevated mitogenic activity ratios of prepartum versus postpartum plasma antedate the clinical recognition of preeclampsia, and return to normal with the resolution of the syndrome. (AM J OBSTET GYNECOL 1990;163:1839-44.)

Preeclampsia is a pregnancy-specific disorder of uncertain cause and pathophysiology. Particular aspects of the pathologic changes associated with the syndrome of preeclampsia suggest that generalized maternal vascular endothelial cell dysfunction could explain the vasospasm, edema, proteinuria, coagulopathy, and renal and hepatic abnormalities that are hallmarks of this disease.[1] A variety of clinical observations lends credence to the hypothesis of endothelial cell injury in this syndrome. The pathognomonic renal lesion found in women with preeclampsia, glomeruloendotheliosis,[2] provides morphologic evidence of maternal endothelial cell perturbation in this condition, whereas elevations

of plasma fibronectin[3] and factor VIII antigen[4] and decreased levels of prostacyclin[5] reflect biochemical dysfunction in these cells. Finally, the increased rate of disappearance of circulating Evans blue dye[6] suggests that the functional integrity of maternal endothelia is altered in preeclampsia. That these changes might be caused by a circulating factor is suggested by our finding that predelivery sera from women with preeclampsia injure human endothelial cells in vitro.[7] We have also found that mitogenic activity is increased in prepartum blood obtained from these patients.[8] We hypothesized that increased growth factor activity was a result of the direct release of mitogens from injured endothelial cells or platelet activation by perturbed endothelium.[9] Our previous studies demonstrated the presence of this activity in women with overt preeclampsia. This study was designed to determine whether increased mitogenic activity antedated the clinical syndrome of preeclampsia.

Material and methods

Patient selection. All pregnant women who registered for prenatal care at the affiliated hospitals of the University of California, San Francisco, were invited to participate in a prospective study of preeclampsia. Among those who entered the study in 1988, a cohort of 12 primigravid women (six normal and six preeclamptic singleton pregnancies; see below) with complete clinical and biochemical data were studied. All participating patients gave written informed consent to donate serial plasma samples for the purpose of the study. The blood samples were obtained at the times of routine clinical testing, starting no later than the first trimester of pregnancy. Plasma was prepared within 12 hours of venipuncture, and aliquots were stored at −70° C. In this study patients had from four to eight plasma samples (mean, 6) obtained throughout pregnancy, with each trimester represented. Thus the quantification of growth factor activity in these pregnancies represents the analysis of 65 individual plasma samples. Demographic and clinical data were collected at routine obstetric visits. All patients were followed throughout the pregnancy until at least 6 weeks post partum.

A panel of five obstetricians reviewed the clinical course of each patient and a post hoc assignment was made to normal or preeclampsia groups. Rigid criteria, as recommended by Chesley,[10] were established for the diagnosis of preeclampsia. Patients with preeclampsia were defined as follows: nulliparous, not known to be hypertensive before pregnancy, manifesting an increase in systolic pressure of 30 torr or diastolic pressure of 15 torr (or an increase in mean arterial blood pressure [MAP] >20 torr) compared with blood pressures obtained before 20 gestational weeks, proteinuria ≥0.5 gm/24 hours or ≥30 mg/dl by dipstick of catheterized urine, serum uric acid level >5.5 mg/dl, return to normal blood pressure and clearance of proteinuria by 12 weeks post partum. Normal, control patients were matched with those with preeclampsia for race and gestational age at delivery. Patients with evidence of illicit drug or cigarette use, chronic hypertension, or any other medical diseases were excluded.

Growth factor (mitogenesis) bioassay. Quiescent cultures of human foreskin fibroblasts were used in the growth factor bioassay optimized and described previously.[8] A total of 65 aliquots of frozen plasma were gently thawed at room temperature and diluted to a final concentration of 2% in Dulbecco's modified Eagle's medium, supplemented with Hepes (20 mmol/L), bovine serum albumin (500 μg/ml), transferrin (5 μg/ml), insulin (1 μg/ml), and heparin (2 U/ml). Samples were never subjected to more than one thaw. The plasma-reconstituted media were added to triplicate wells of cultured fibroblasts. Incorporation of tritiated thymidine into deoxyribonucleic acid of these cells was determined after precipitation of the nucleic acids with 10% trichloroacetic acid, and liquid scintillation counting of the resuspended precipitate was performed. To correct for individual variation in the growth factor analyses, the results of each plasma sample mitogenic activity are expressed as a multiple of the same patient's immediate postpartum sample, as described previously.[8] In the aforementioned study, Musci et al.[8] demonstrated that differences between the mitogenic activities of preeclamptic and normal blood samples were present in predelivery but not postpartum specimens. Thus normalization to the immediate postpartum growth factor activity of each patient resulted in a "mitogenic index" to be compared among all patients. Furthermore, to minimize bias in the bioassays, sets of samples from normal patients and those with preeclampsia were always measured simultaneously within the same fibroblast cultures. Average mitogenic indices for each trimester of pregnancy were calculated from the pooled results of samples obtained from each patient during that trimester.

Statistical analysis and interpretation. Study results are presented as the mean values (±SD) of each clinically defined group. The results of blood pressure determination and analyses of proteinuria throughout the course of pregnancy were collected from the patients' prenatal records. The MAP for each patient at term was derived from the average of at least four independent readings during the last week of pregnancy, according to the calculation: MAP = Diastolic + ([Systolic − Diastolic]/3). Average MAP and urine protein concentration determinations were quantified for each patient in each trimester of pregnancy. Comparisons between the two study groups (12 subjects in total) were made with the nonparametric

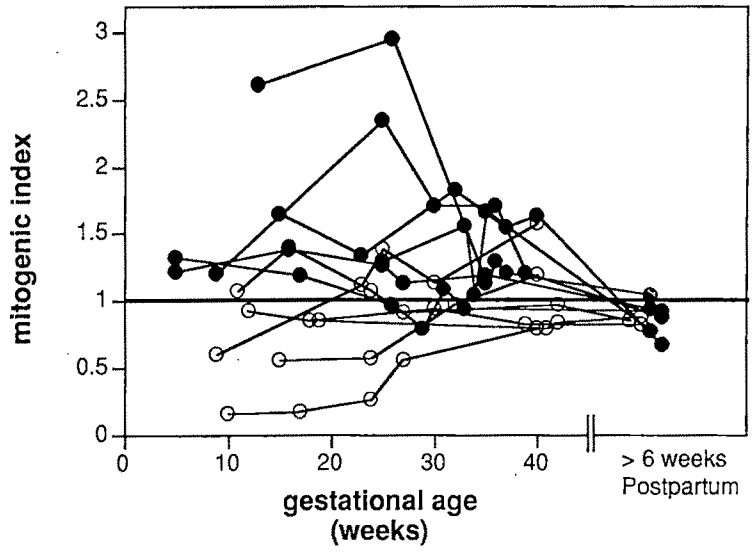

Fig. 1. A total of 65 plasma samples collected longitudinally throughout pregnancy from 12 patients were assayed for mitogenic activity as described in Material and methods. Mitogenic indices were computed and normalized by each patient's immediate postpartum sample as described. The indices are plotted against the time of blood sampling (weeks of gestation from last menses). Patients who ultimately met strict criteria for the diagnosis of preeclampsia are represented with *closed circles*, whereas matched normal pregnant women are indicated by *open symbols*. The mitogenic indices of each individual patient are connected by lines. Postpartum plasma samples were obtained at >6 weeks after delivery.

Table I. Patient characteristics and intrapartum clinical data

	Preeclamptic ($n = 6$)	*Normal* ($n = 6$)	p*
Maternal age at delivery (yr)	25 ± 5†	30 ± 5	NS
Parity	0	0	NS
Infant weight at delivery (gm)	2507 ± 884	3277 ± 453	NS
Gestational age at delivery (wk from last menses)	37 ± 5	39 ± 2	NS
Hematocrit (%, vol/vol)	37 ± 2	37 ± 5	NS
Serum creatinine (mg/dl)	0.7 ± 0.2	0.6 ± 0.2	NS
Mean arterial pressure (torr)	108 ± 7	80 ± 7	<0.01

†Mean ± SD.

‡Semiquantitative dipstick analysis of catheterized urine samples.

Mann-Whitney test; values of $p < 0.05$ were considered to reflect significant differences.

Results

The clinical and biochemical findings of the patients at term are shown in Table I. As anticipated by the diagnostic criteria used to identify women as having preeclampsia, this group of parturients had elevations in mean arterial blood pressure and proteinuria ($p < 0.01$) and serum uric acid concentrations ($p < 0.02$) compared with matched normal controls. In addition, trends toward lower maternal age and decreased infant birth weight were noted in the patients with preeclampsia (Table I).

The longitudinal patterns of growth factor activity, as determined by the mitogenesis bioassay, demonstrated significant differences between pregnancies that were ultimately identified as normal and preeclamptic. The data presented in Fig. 1 demonstrate the mitogenic indices determined throughout pregnancy for each of the 12 study patients. The majority of women who ultimately met strict criteria for the diagnosis of preeclampsia had prepartum plasma mitogenic indices >1. By contrast, mitogenic indices for matched normal

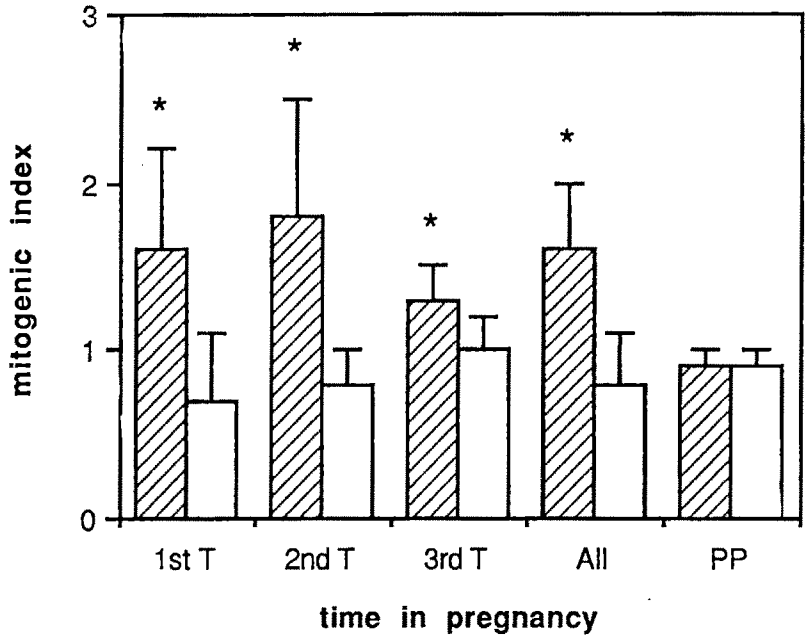

Fig. 2. Mitogenic indices (predelivery/postdelivery counts per minute incorporated per well of human fibroblasts) of prospectively collected plasma were quantified throughout pregnancy and postpartum by use of tritiated thymidine incorporation assays as described in Material and methods. The mean (±SD) mitogenic indices averaged over each of the three trimesters *(T)*, the entire pregnancy *(All)*, and at >6 weeks post partum *(PP)* are shown. Patients ultimately diagnosed with preeclampsia are represented by the *hatched bars*, whereas the matched normal parturients are represented by *open bars*. Histograms indicate data from all 12 patients in the second, third, and *All* trimester categories. Data from four patients in each group are shown in the first trimester, and six women with preeclampsia and three normal patients are represented in the >6 weeks postpartum data. *Asterisk* indicates values that are different from those of normal parturients by Mann-Whitney tests ($p < 0.05$).

Table II. Longitudinal assessment of blood pressure, proteinuria, and growth factor activity during pregnancy

	First trimester	*Second trimester*	*Third trimester*
Mean arterial pressure (torr)			
Preeclamptic	81 ± 8	88 ± 7	101 ± 7
Normal	78 ± 8	77 ± 5	78 ± 5
p*	NS	<0.05	<0.01
Proteinuria (mg/dl)			
Preeclamptic	0	0	48 ± 29
Normal	0	0	0
p*	NS	NS	<0.01
Mitogenic index (ratio)			
Preeclamptic	1.6 ± 0.6	1.8 ± 0.7	1.3 ± 0.2
Normal	0.7 ± 0.4	0.8 ± 0.2	1.0 ± 0.2
p*	<0.05	<0.01	<0.02

*Level of significance by Mann-Whitney test.

women were generally <1. By this index growth factor activity appeared greatest in plasma collected during the first two trimesters of pregnancy from women in whom preeclampsia ultimately developed (Fig. 1).

To statistically evaluate these data, we calculated the average mitogenic index for each patient during the entire pregnancy, independently for each of the three trimesters, and during a late postpartum period (>6 weeks from delivery). Thus no patient was represented more than once in a given gestational period, even if multiple plasma samples were tested within a single trimester. Because the distribution of the average mitogenic index for each subject was not known to be normally distributed, analysis by the nonparametric Mann-Whitney test was selected. Women predestined to meet criteria for the diagnosis of preeclampsia had significantly elevated mitogenic indices throughout pregnancy compared with matched normal primigravid women (1.6 ± 0.4 vs 0.8 ± 0.3, mean ± SD, $p < 0.01$; see Fig. 2). Similar statistical analyses of growth factor activity for each trimester of pregnancy distinguished women in whom preeclampsia developed from their normal peers in each trimester (first trimester, 1.6 ± 0.6 vs 0.7 ± 0.4, $p < 0.05$; second trimester, 1.8 ± 0.7 vs 0.8 ± 0.2, $p < 0.01$; third trimester, 1.3 ± 0.2 vs 1.0 ± 0.2, $p < 0.02$; Fig. 2). The results of the third-trimester analyses confirmed our initial report of mitogenic indices in preeclamptic and normal pregnancy sera at term (1.4 ± 0.2 vs 1.1 ± 0.2, $n = 29$, $p < 0.01$).[8] Despite significant differences between the

normal and preeclamptic groups before delivery, however, by 6 weeks post partum both groups had indistinguishable mitogenic indices (0.9 ± 0.1 vs 0.9 ± 0.1; Fig. 2).

Longitudinal analyses of mean arterial blood pressures and proteinuria in the same patients are presented in Table II. A statistically significant difference between the average MAP of the preeclamptic and normal groups was demonstrable by the second trimester of pregnancy (88 ± 7 vs 77 ± 5 torr, $p < 0.05$). The MAP values in these groups corresponded to average blood pressures of 125/74 and 106/63 torr in women with preeclampsia and normal patients, respectively. However, the elevation of MAP in the preeclamptic group only achieved a diagnostically significant level during the third trimester of pregnancy (101 ± 7 vs 78 ± 5 torr, $p < 0.01$), reflecting average blood pressures of 144/81 and 112/64 torr. Differences in proteinuria between the two groups were noted only in the third trimester (Table II).

Comment

We used strict diagnostic criteria in patient selection, analyses of multiple, longitudinally collected samples from the same cohort of patients, and calculation of a plasma mitogenic index by normalizing to each woman's immediate postdelivery plasma growth factor activity. As shown in Fig. 1, this strategy resulted in the resolution of 65 individual plasma samples into two clusters with minimal overlap that corresponded to pregnancy outcome despite the limited number (12) of study subjects. Moreover, when the data were combined according to trimester of pregnancy, conservative, nonparametric statistical analyses demonstrated that the plasma mitogenic indices in normal and preeclamptic pregnancies differed throughout gestation (Fig. 2).

The results of this study confirm our earlier finding[8] that the mitogenic index is elevated in the blood of women with the classic syndrome of preeclampsia in relation to appropriately matched, normal controls. In addition, this study revealed that elevated mitogenic indices of preeclamptic plasma were demonstrable months before the patients satisfied the clinical diagnosis of preeclampsia. Finally, differences in mitogenic index between the two patient groups disappeared by 6 weeks post partum, when clinical and biochemical evidence of the syndrome were no longer detectable. This is an especially important point because it excludes the possibility that the mitogenic index was increased in women with preeclampsia because of a temporary reduction in mitogenic activity in the immediate postpartum period. In addition, this finding suggests that altered mitogenic activity is a result of preeclampsia rather than a predisposing factor.

Several clinical and biochemical tests, including plasma fibronectin levels,[3] circulating factor VIII activity,[4] and response to angiotensin II infusion,[11] can identify women at risk for the development of preeclampsia by the midtrimester. Similar to the recent report on elevated levels of cellular fibronectin in preeclampsia,[12] the mitogenic index appears to statistically differentiate the group of patients in whom preeclampsia will develop as early as the first trimester of pregnancy. Because the most important pathophysiologic abnormalities of preeclampsia (poor trophoblast invasion and reduced placental perfusion[1]) are established early in pregnancy, it is not surprising that fundamental biochemical changes associated with this syndrome should also be detectable at this time.

Because the release of mitogenic growth factor activity is commonly associated with endothelial damage, these studies support our hypothesis that endothelial cell injury is an early, pathogenetic feature of preeclampsia.[1] Studies are currently underway to ascertain the identity and origin of the mitogenic activity. Partial purification of the mitogen(s) has indicated that this is a heat- and acid-labile protein with an apparent native molecular weight of 150,000.[13] This size is significantly larger than the classic growth factors and placental proteins with known trophic effects (e.g., human placental lactogen). However, the apparent molecular weight of this molecule(s) may reflect binding of a known growth factor to a plasma carrier protein, as in the case of insulin-like growth factors.[14] Future studies will attempt to ascertain how abnormal placentation, endothelial cell injury, and plasma mitogenic activity are linked in the pathophysiology of this puzzling syndrome.

We thank Mitra Jazayeri, Jean Perry, Alan Goldfien and the physicians of the Clinical Data Core for their support and expertise.

The effect of nifedipine therapy on fetal and placental Doppler waveforms in preeclampsia remote from term

Michael M. Moretti, MD, Fiona M. Fairlie, MD, Sherif Akl, MD, Aldo D. Khoury, MD, and Baha M. Sibai, MD

Memphis, Tennessee

Twenty patients with preeclampsia at a gestational age of 26 to 35 weeks were treated with oral nifedipine until delivery. The mean oral daily dose was 45.1 ± 11 mg/day (range, 40 to 80 mg/day). Fetal aorta, internal carotid artery, umbilical artery, and uteroplacental Doppler flow velocity waveforms were recorded before treatment and then serially. The mean nifedipine concentration at the time of the Doppler studies was 60.3 ng/ml (range, 10 to 90 ng/ml). The use of nifedipine therapy was associated with a significant decrease in both maternal systolic blood pressure (baseline, 154 to 135 mm Hg, $p < 0.001$) and diastolic blood pressure (baseline, 100 to 88 mm Hg, $p < 0.001$). However, there was no significant difference in the resistance index between baseline and postnifedipine Doppler studies in either the fetal or uteroplacental vessels. The use of oral nifedipine to control blood pressure in preeclampsia does not affect the resistance indices in fetal or uteroplacental vessels as measured by the Doppler technique. (AM J OBSTET GYNECOL 1990;163:1844-8.)

Key words: Preeclampsia, nifedipine, Doppler velocity waveforms

Nifedipine, a dihydropyridine calcium channel blocker, is a particularly effective antihypertensive agent.[1] The use of calcium channel blockers in the pregnant animal model was reportedly associated with a decrease in placental blood flow and development of fetal hypoxemia and acidosis.[2-6] However, their use to treat preterm labor and in the management of hypertensive disorders of pregnancy was not associated with any reported adverse perinatal outcome.[7-10]

Three reports described the acute effects of calcium channel blockers on fetal and uteroplacental circulations in hypertensive pregnancies. All three studies evaluated the effects of a single dose of either nifedipine ($n = 2$)[8, 10] or nicardipine ($n = 1$).[9] None of these studies reported any adverse effects on either fetal or uteroplacental circulations. In addition, Mari et al.[7] reported the effects of nifedipine therapy for preterm labor and concluded that short-term nifedipine therapy did not influence either fetal or uteroplacental circulation as evaluated with Doppler technique. To date, there are no reports describing the effects of long-term oral nifedipine therapy on fetal and uteroplacental circulations.

The purpose of this study was to examine the effects on fetal and uteroplacental Doppler velocimetry waveforms of long-term oral nifedipine therapy in patients with preeclampsia remote from term.

Material and methods

The study was performed at E.H. Crump Women's Hospital and Perinatal Center between 1988 and 1989.

From the Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, University of Tennessee, Memphis.
Presented at the Thirty-seventh Annual Meeting of the Society for Gynecologic Investigation, St. Louis, Missouri, March 21-24, 1990.

6/6/24730

The study population included 20 patients with documented preeclampsia. All patients gave written consent for the study, which was approved by the Institutional Investigational Review Board. Entry criteria included the following: maternal age ≥15 years, gestational age between 26 and 35 weeks with a persistent maternal systolic blood pressure range of 140 to 170 mm Hg and a diastolic blood pressure range of 90 to 110 mm Hg 24 hours after hospitalization, the development of proteinuria ≥300 mg/24 hours, and documented normal first-trimester blood pressure readings. The exclusion criteria of the study included the presence of twins, diabetes mellitus, Rh isoimmunization, and congenital fetal malformation. In addition, any pregnancy complicated by signs of intrauterine growth retardation or fetal distress was excluded. Intrauterine growth retardation was defined as an estimated fetal weight by ultrasonographic measurement of head circumference and abdominal circumference below the 10th percentile for our population standards.

All patients were admitted to the antepartum unit and placed at bed rest. Blood pressure measurements were performed four times daily. No other medications were used except prenatal vitamins and iron supplementation.

Nifedipine therapy was started at 10 mg orally every 6 hours (40 mg/day) and increased to a maximum dosage of 80 mg/day. The dosage was titrated to keep the systolic blood pressure <140 mm Hg and diastolic blood pressure <90 mm Hg. Serum nifedipine levels were tested after at least 48 hours (eight doses) of dosing to achieve steady state and at the time of Doppler studies.

Baseline Doppler studies were performed immediately before treatment, repeated after steady state (48 hours), and then at 3-day intervals until delivery. Doppler studies were scheduled for 1 hour after the midday nifedipine dose. The Doppler ultrasonographic studies were done with an Ultramark 9 (ATL) system. A 50 Hz wall filter was used; Doppler ultrasonographic energy was 114 mw/cm^2 spatial peak temporal average intensity. The fetuses were examined with the mothers in semirecumbent position. The uterine arteries were studied with continuous-wave technique as described by Schulman et al.[11] Measurements from both uterine vessels were obtained and the results were averaged. Umbilical arteries were studied by pulsed Doppler with the sample volume placed in a free loop midportion of the cord. The fetal descending aorta was examined in the absence of fetal breathing movements at a point just above the level of the diaphragm with the transducer oriented to maintain the angle of insonation between 40 and 60 degrees. A sufficiently large sample volume was chosen to completely cross the aorta but not to provide interference with other vessels. Waveforms were recorded over a 5-second period that included an average of 10 consecutive cadiac cycles. Doppler velocity waveforms of the intracranial portion of the fetal internal carotid artery at the level of the bifurcation into the middle and anterior cerebral artery were recorded by the method described by Wladimiroff et al.[12] To determine these waveforms, we obtained the standard plane for measuring the biparietal diameter. The transducer was then moved parallel down to the base of the skull until a plane was reached that demonstrated the brain stem with the cerebral peduncles. Anterior to the heart-shaped brain stem on either side of the midline, a cross-section of the internal carotid artery as it divides into the anterior and middle cerebral vessels was seen pulsating. Color flow Doppler was used to help define these vessels. The sample volume (4 mm) was placed over the internal carotid artery and the maximum systolic velocity was recorded. Doppler waveforms were quantified by calculating the resistance index (Peak systolic velocity − Diastolic velocity/Peak systolic velocity).

Delivery data included placental weight, birth weight, Apgar scores, and cord arterial blood gases. Results were analyzed with analysis of variance for repeated measurements. A probability value of <0.05 was considered to indicate statistical significance.

Results

A total of 20 patients were studied; 16 were primigravid and four were multigravid women. The mean maternal age was 23 ± 6.23 years. Relevant clinical findings of the study patients are summarized in Table I. The mean nifedipine dose was 45.1 mg/day, and the mean interval between starting treatment and the first postdrug Doppler study was 95 hours. The mean maternal serum nifedipine concentration performed at the time of Doppler studies was 60.3 ng/ml (range, 10 to 90 ng/ml). Nifedipine therapy was associated with a significant decrease in maternal blood pressure. Mean systolic pressure decreased from 154 to 135 mm Hg ($p < 0.001$). Mean diastolic pressure decreased from 100 to 88 mm Hg ($p < 0.001$).

Results of the Doppler studies are summarized in Table II. All pretreatment and posttreatment Doppler results were within 1 SD of the mean for our normal population. There was no significant change in the resistance index between the baseline and Doppler studies performed at 4 days after nifedipine therapy. In addition, there were no differences in the resistance indices in subsequent measurements (by analysis of variance for repeated measurements).

Perinatal outcomes are listed in Table III. There were four (20%) small-for-gestational-age infants. Among these four pregnancies, maternal mean systolic pressure decreased from 156 to 131 mm Hg and mean

Table I. Clinical findings ($N = 20$)

	Mean ± SD	*Range*
Admission gestational age (wk)	31.0 ± 3.1	26-35
Delivery gestational age (wk)	33.9 ± 3.4	31-39
Pregnancy prolongation (days)	21.4 ± 20	5-84
Dose of nifedipine (mg/day)	45.1 ± 11	40-80

Table II. Doppler studies (resistance index)

	Baseline (mean ± SD)	*Treatment* (mean ± SD)*
Umbilical artery	0.61 ± 0.1	0.70 ± 0.8
Uterine artery	0.59 ± 0.1	0.57 ± 0.15
Descending aorta	0.85 ± 0.04	0.84 ± 0.05
Internal carotid artery	0.77 ± 0.08	0.69 ± 0.11

*At time of initial Doppler measurement performed an average of 4 days after therapy.

diastolic blood pressure decreased from 96 to 83 mm Hg in response to nifedipine therapy. These changes were not significantly different to the group as a whole. One infant had an acidotic cord arterial pH. This infant was delivered by cesarean section at 28 weeks' gestational age because of repetitive variable decelerations in labor.

Comment

Preeclampsia is a disease that is unique to human pregnancy, with an unknown cause. Despite recent progress in understanding its pathophysiology, the available therapeutic tools remain limited to either bed rest or delivery. Thus there remains an important place for the development of new approaches, such as calcium channel blockers, to the management of preeclampsia.

The results of a number of animal studies with calcium channel blockers are concerning. In addition, in both animal and human investigations there is a heterogeneity with regard to the specific calcium channel blockers studied. Although both nifedipine and nicardipine are dihydropyridine calcium channel blockers, they are biochemically different.[15] Caution should be exercised in extrapolating the effects of nicardipine to nifedipine. Parisi et al.[2,3] studied the effects of maternal nicardipine therapy on fetal placental blood flow and cardiorespiratory status in the hypertensive pregnant ewe. After maternal infusion of angiotensin II, nicardipine was infused and fetal and maternal blood flow were measured. Nicardipine reversed maternal hypertension but placental blood flow decreased and vascular resistance increased. They noted the death of five of 15 fetuses 65 minutes after nicardipine infusion. Ducsay et al.[4] administered nicardipine to spontaneously

contracting rhesus monkeys and noted the development of fetal acidosis and hypoxemia. Ahokas et al.[14] used a different calcium channel blocker, nifedipine, and found that blood flow was not significantly altered by nifedipine in the spontaneously hypertensive rat.

There have been three reports of studies of the effects of calcium channel blockers on the uteroplacental and umbilical circulations in hypertensive human pregnancies. Cameron et al.[9] studied the effects of nicardipine when used for the acute reduction of blood pressure in patients with preeclampsia. There were no significant alterations in either the pulsatility index or resistance index of the uteroplacental or umbilical vessels within 60 minutes of a single oral dose of nicardipine. Lindow et al.[8] determined an index of uteroplacental blood flow by use of a radioisotope method. There was no significant change in the blood flow index after a single dose of nifedipine despite a significant fall in blood pressure. In addition, Hanretty et al.[10] were unable to demonstrate a change in Doppler waveforms within 8 hours of a single 20 mg oral dose of nifedipine in nine pregnant women with proteinuric hypertension. Recently Mari et al.[7] performed Doppler studies of the uteroplacental and fetal circulations in patients with preterm labor who were treated with nifedipine for tocolysis. No significant difference was found in flow velocity waveforms 5 hours after the initial dose. The results of these studies suggest that short-term nifedipine therapy does not influence fetal or uteroplacental circulations.

This study was designed to investigate the effects of long-term oral nifedipine therapy on the uteroplacental and fetal circulations in hypertensive pregnancies by means of the Doppler technique. In our study long-term oral nifedipine therapy was associated with a significant decrease in maternal blood pressure. We were unable to demonstrate a significant difference in the resistance indices between baseline and first postnifedipine Doppler studies. In addition, when performed serially, there was no significant change in subsequent Doppler indices in any of the vessels studied. Although we were unable to demonstrate a change in resistance

as measured by the Doppler technique, it should be noted that there may still be a decrease in perfusion or flow to the vascular beds studied, based on a decrease in perfusion pressure to the uteroplacental circulation. This may not be manifested by a change in the Doppler resistance indices. Trudinger et al.[15] compared Doppler flow velocity waveforms with microsphere blood flow data in the umbilical placental circulation after the administration of the vasodilator prostacyclin. They observed a fall in the systolic/diastolic ratio of the fetal umbilical artery as measured by the Doppler technique. However, measurements of the umbilical placental blood flow by the radioactive microsphere technique showed a decrease in umbilical placental blood flow. Their results were similar to those of Parisi and Walsh,[15] who demonstrated a fall in fetal mean arterial pressure during prostacyclin infusion. Placental blood flow decreased, whereas vascular resistance was unchanged. Thus there could be a potential decrease in flow as a result of decreases in perfusion pressure. This could occur in the absence of alterations in resistance as measured by the Doppler technique. However, increases in the resistance index and systolic/diastolic ratio of uteroplacental circulation (as measured by the Doppler technique) have been associated with adverse pregnancy outcome. There were no significant changes in any of the vessels studied in response to treatment. This is further supported by the overall favorable perinatal outcome of the group.

It should be noted that all pretreatment Doppler study results were normal for gestational age. In addition, none of the pregnancies was complicated by signs of fetal growth failure or fetal compromise before the start of therapy, as determined by ultrasonographic measurements and biophysical testing. Thus the effect of long-term nifedipine therapy in hypertensive pregnancies with such complications cannot be established by these data. However, it must be noted that four (20%) of the infants were small for gestational age at delivery, and none demonstrated a significant change in the Doppler waveforms in any of the vessels studied. In addition, no fetus had signs of fetal distress in the antepartum period.

It has been demonstrated in the lamb model that the fetus responds to hypoxemia and acidemia with a redistribution of cardiac output from the splanchnic circulation that results in an increase in flow to the brain and heart. Low peripheral resistance in the nonhypoxic state is replaced by selective vasoconstriction mediated by α-adrenergic innervation to the gut, kidney, and lung.[17, 18] Our results show no significant change in the resistance index of the cerebral vessels or descending aorta. This lack of change suggests that there was no significant redistribution of cardiac output as a result of fetal hypoxemia. This is further supported by the perinatal outcome in our study group; only one infant had an acidotic cord arterial pH at delivery.

Plasma levels of nifedipine were performed at the time of Doppler studies. The first Doppler studies were performed 48 hours after the start of therapy to measure flow velocity waveforms in the steady state. Doppler studies were scheduled 1 hour after the midday dose. Maximum activity concentration in the serum are reached 1 to 2 hours after administration of nifedipine.[19] Thus, although we regret that we cannot report the Doppler findings at initial peak serum levels, efforts were made to perform the Doppler studies at a time of maximum activity concentration. Maternal plasma nifedipine levels ranged from 10 to 90 ng/ml. Therapeutic effects of nifedipine have been reported with plasma values as low as 3 ng/ml.[19] This demonstrates that nifedipine did not influence Doppler waveforms when present in the maternal circulation in therapeutic concentrations. This is further supported by the significant decrease in maternal blood pressure during therapy.

We conclude that long-term oral nifedipine therapy in patients with preeclampsia effectively controls maternal hypertension with no effect on fetal or uteroplacental Doppler indices. Whether the same results can be obtained during the chronic use of nifedipine in pregnancies complicated by fetal growth failure or compromise remains to be established.

Neuroophthalmologic effects of intravenous magnesium sulfate

Kathleen B. Digre, MD,[a] Michael W. Varner, MD,[b] and Jade S. Schiffman, MD, LTC, MC, USA[c]

Salt Lake City, Utah, and San Francisco, California

To test the hypothesis that visual disturbances are more common during intravenous magnesium sulfate administration than at 1 to 4 days after discontinuation of the drug, 13 women underwent beoside neuroophthalmologic examinations during intravenous magnesium sulfate tocolysis at 2.0 to 3.0 gm/hr and again at 1 to 4 days after cessation of therapy. Visual symptoms were common during intravenous magnesium sulfate administration. Blurred vision was present in 12 of 13 patients and diplopia was present in 10 of 13 patients. Abnormal findings during neuroophthalmologic examination occurred in all patients during intravenous magnesium sulfate administration. Findings included ptosis, accommodative and convergence insufficiency, and abnormal pupillary responsiveness to light and near. All patients were symptom-free and had normal examinations after magnesium sulfate was discontinued. These findings suggest that visual disturbances with therapeutic magnesium sulfate are common. (AM J OBSTET GYNECOL 1990;163:1848-52.)

Key words: Magnesium sulfate, neuroophthalmology, visual disturbances

Intravenous magnesium sulfate is routinely administered in the United States to pregnant women with preeclampsia and eclampsia for seizure prophylaxis. Visual disturbances are sometimes seen in patients with preeclampsia and are considered a distinguishing criterion for severe disease.[1] In our population the most common visual symptoms associated with severe preeclampsia include visual blurring and visual field defects.[2] Visual disturbances in preeclampsia may be due to choroidal ischemia with serous retinal detachment (with or without evidence of other manifestations of hypertensive retinopathy) or cerebral vasospasm. However, the neuroophthalmologic effects of intravenous magnesium sulfate also could be responsible for visual symptoms. This possibility was suggested to us by the high frequency with which we have encountered visual complaints in pregnant women on our service receiving intravenous magnesium sulfate tocolysis. Recent studies have demonstrated that intravenous magnesium sulfate is an efficacious and relatively safe tocolytic agent with visual complaints reported infrequently.[3-6] Most patients with severe preeclampsia receive magnesium sulfate. As we were not certain which ophthalmologic

symptoms and signs were due to magnesium sulfate alone, we decided to test the hypothesis that patients receiving intravenous magnesium sulfate tocolysis have more frequent visual signs and symptoms than at 1 to 4 days after discontinuation of the drug. The study design was approved by the Human Subjects Study Institutional Review Board of the University of Utah School of Medicine. Informed written consent was obtained from all patients before their entry to this study.

Material and methods

Patients admitted in premature labor to the Obstetric Service of the University of Utah Hospital between July 1, 1987, and April 15, 1989, were evaluated. On our service tocolysis is generally recommended for women presenting in labor before 35 weeks' gestation who have no maternal contraindications to continuing pregnancy and who have an appropriately grown, non-anomalous, immature, healthy fetus. Although β-sympathomimetic medications represent the usual initial tocolytic agent on our service, intravenous magnesium sulfate is occasionally used as the initial drug and may be given as an alternative tocolytic drug if a patient does not respond to β-sympathomimetics or experiences unacceptable side effects.

Our protocol for intravenous magnesium sulfate tocolysis is identical to that described by Dudley et al.[6] and consists of a 4.0 gm loading dose administered over 15 to 20 minutes, followed by a continuous intravenous infusion pump administration of 2.0 gm/hr. If patients are clinically stable but require extended magnesium sulfate tocolysis, they may be transferred to the antepartum ward if the dosage is ≤2.5 gm/hr. Higher levels require continued observation in the labor and delivery area. All patients receiving magnesium sulfate tocolysis on our service are assessed at least every 4 hours for routine vital signs, presence and nature of deep tendon reflexes, and subjective complaints of weakness, nausea, fatigue, headache, visual disturbances, difficulty breathing, chest pain, confusion, and difficulty with concentration.

Patients who were clinically stable yet required continued intravenous magnesium sulfate tocolysis were approached for entry into the study. Criteria for exclusion included coexistent administration of other tocolytic drugs, evidence of regular uterine activity within the preceding 12 hours, a history or evidence of underlying renal disease, coexistent preeclampsia, or the requirement of >2.5 gm/hr of intravenous magnesium sulfate tocolysis. Additionally, patients with a preconceptional history of decreased vision or stabismus were excluded from the study. Thirteen women qualified and consented to our study. They ranged from 13 to 35 years old (mean, 27.8 years). These patients were carefully interviewed during and after magnesium sulfate tocolysis. Specific questioning was done in regard to blurring at distance or near (monocular impairment of vision) and double vision (diplopia or binocular impairment of vision) at distance, near, or any particular gaze direction. Patients were also asked about scotomas or phosphenes.

A bedside neuroophthalmologic examination was performed on each woman during intravenous magnesium sulfate administration (study examination). The entire examination was repeated 1 to 4 days after the medication was stopped (control examination). In this fashion each woman served as her own control. Specific details of the neuroophthalmologic examination are available from the authors on request.

Statistical analysis was performed with the χ^2 analysis for discrete variables and Student's t test, with the Yates correction, for continuous variables. Statistical significance was defined by a p value <0.05.

Results

Serum magnesium levels at the time of study examination averaged 6.1 mg/dl, ranging from 4.7 to 7.4 mg/dl. As listed in Table I, visual symptoms were common in women receiving intravenous magnesium sulfate tocolysis. Other non-visual-tract symptoms were also common at the study examination, although all symptoms had resolved by the time of control reexamination.

All patients had clinically normal deep tendon reflexes, respiratory rates, and heart rates at study and control examinations.

With the exceptions of the Amsler grid, visual fields, versions, and pursuits, visual signs were all significantly affected during intravenous magnesium sulfate tocolysis (Table I). All abnormalities returned to values consistent with those of normal, healthy young women at the time of control reexamination.

Comment

Our protocol for magnesium sulfate tocolysis is identical to that of previous reports and our average serum levels correlate well with the data of others.[3,4] These levels are also within the generally accepted therapeutic range for seizure prophylaxis in women with preeclampsia.[1]

The adverse effects of hypermagnesemia that are commonly discussed include decreased deep tendon reflexes, muscle weakness, respiratory depression, and cardiac arrhythmias. With the exception of muscular weakness, none of these adverse effects were encountered, consistent with the previous observation that magnesium sulfate is associated with a low frequency of serious complications when carefully administered to appropriate candidates.[7]

In spite of our apparently similar drug administra-

NPA, Near point of accommodation; *OD*, right eye; *OS*, left eye.

tion protocol, we have encountered a much higher incidence of visual signs and symptoms than have other investigators. Hollander et al.[3] reported a finding of diplopia in only two of 33 patients and no other adverse visual effects, and other recent evaluations[7,8] did not report any adverse visual signs or symptoms.

Our patients experienced frequent visual complaints (blurred vision, double vision) during a magnesium sulfate tocolysis protocol where the dose was similar to that of the aforementioned authors. It is unclear why we should have such different findings, although the possibility certainly exists that specific questioning may have increased the incidence of positive responses.

We found a consistent pattern of neuroophthalmologic abnormalities during intravenous magnesium sulfate administration. The most striking finding was bilateral symmetric ptosis. Levator function was normal, suggesting a supranuclear mechanism.

Fusional convergence amplitudes were less than half of control measurements. A less dramatic, but significant finding was the decrease in fusional divergence amplitudes during magnesium sulfate administration. The fact that both convergence and divergence amplitudes were diminished in the setting of grossly normal versions also speaks for a supranuclear disturbance in the control of motor fusion.

We found that the majority of our patients had an exodeviation at near. This, combined with poor fusional convergence amplitudes, defined convergence insufficiency in our patients. This is also a presumably supranuclear disturbance. Additionally, all patients had a remote near point of accommodation and therefore had an accommodative insufficiency. The accommodative insufficiency could result from either a supranuclear or a peripheral site of dysfunction.

We hypothesize that intravenous magnesium sulfate causes neuroophthalmologic dysfunction and that both central and peripheral mechanisms may be involved. The abnormalities of convergence, accommodation, and pupillary testing also suggest both central and peripheral mechanisms. Further studies will be required to determine what proportion of these changes is mediated by peripheral effects of magnesium sulfate on the myoneural junction and what proportion might be

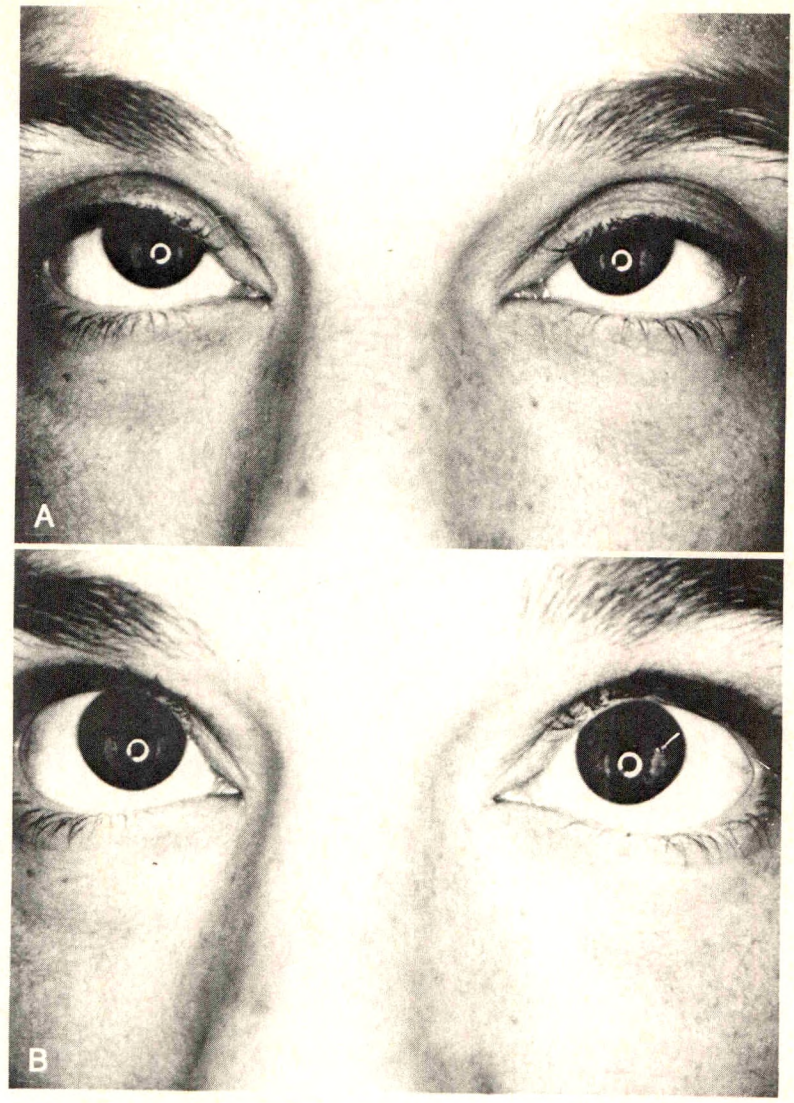

Fig. 1. Standardized Polaroid photographs of the same woman **(A)** while receiving intravenous magnesium sulfate tocolysis and **(B)** at control reexamination (after intravenous magnesium sulfate tocolysis).

mediated via central effects. Such studies might also provide valuable insights into the potential anticonvulsant effects of magnesium sulfate.

We have presented the ophthalmologic symptoms and signs of intravenous magnesium sulfate administration. It is well known that visual symptoms can develop in women with severe preeclampsia and eclampsia and that this may indicate worsening of the condition. As these women are treated with magnesium sulfate, it is important to differentiate the visual complaints from worsening of disease from those of intravenous magnesium sulfate therapy. We have previously found that women with severe preeclampsia and/or eclampsia complain primarily of scotomas (both positive and negative) and/or segmental visual blurring,[2] unlike the complaints of blurred vision and diplopia found in this study. These symptoms were frequently due to associated serous retinal detachments and choroidal infarctions that were not present in the patients in this study. The Amsler grid has been found to be of value in identifying women with preeclampsia who have scotomas and has not demonstrated any abnormalities in women undergoing magnesium sulfate tocolysis.

We have demonstrated visual symptoms and signs associated with intravenous magnesium sulfate administration. Magnesium sulfate produces blurred vision and/or diplopia but is not associated with scotoma or phosphenes. Although blurred vision may be seen in preeclampsia, abnormalities or Amsler grid testing are

more common. This is important to understand, since the obstetrician can usually differentiate between the two by history and simple bedside examination techniques, to make appropriate management decisions. While obstetricians may not be conversationally familiar with all of the definitions and procedures presented in this manuscript, these definitions and procedures represent standard ophthalmologic practice. It is important that obstetricians be aware of the visual abnormalities produced by magnesium sulfate because these abnormalities are common and obvious to careful observation.

Bound volumes available to subscribers

Bound volumes of the American Journal of Obstetrics and Gynecology are available to subscribers (only) for the 1990 issues from the Publisher, at a cost of $56.00 ($79.00 international) for Vol. 162 (January-June) and Vol. 163 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the Journal name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318, USA; phone (800) 325-4177, ext. 7351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular Journal subscription.

Low-dose aspirin

II. Relationship of angiotensin II pressor responses, circulating eicosanoids, and pregnancy outcome

Charles E. L. Brown, MD, Norman F. Gant, MD, Kay Cox, MT(ASCP), Bernard Spitz, MD, Charles R. Rosenfeld, MD, and Ronald R. Magness, PhD

Dallas, Texas

Forty pregnant women (28 to 32 weeks' gestation) were given low-dose aspirin therapy (81 mg/day) from the time of enrollment until delivery; circulating eicosanoid levels and angiotensin II pressor responses were measured before and after 1 week of aspirin therapy. Subsequent clinical outcome was correlated with these results. All women had significant reductions in serum and plasma thromboxane B_2 levels with aspirin treatment ($p < 0.01$). Eleven women who remained sensitive to the pressor effects of angiotensin II (effective pressor dose < 10 ng/kg/min) after 1 week of low-dose aspirin treatment exhibited significant decreases ($p < 0.05$) in plasma 6-keto-prostaglandin $F_{1\alpha}$ (264 ± 119 vs 161 ± 31 pg/ml, mean ± SD) and prostaglandin E_2 (476 ± 174 vs 351 ± 112 pg/ml) levels. In contrast, patients who were either nonsensitive (refractory) to angiotensin II ($n = 18$; ≥10 ng/kg/min) before aspirin or became nonsensitive after aspirin administration ($n = 11$) had no change in either plasma 6-keto-prostaglandin $F_{1\alpha}$ or prostaglandin E_2 concentrations. The occurrence of pregnancy-induced hypertension was 100% in the women who remained angiotensin II sensitive during aspirin therapy as compared with 36% and 39% in the other two groups ($\chi^2 = 16.14$; $p < 0.001$). Thus during low-dose aspirin therapy a failure to develop refractoriness to infused angiotensin II is associated with a nonselective inhibition of eicosanoids and the almost certain development of pregnancy-induced hypertension. These observations may reflect a basic defect in vascular adaptation to pregnancy. (Am J Obstet Gynecol 1990;163:1853-61.)

Key words: Low-dose apsirin, preeclampsia, angiotensin II, pressor responses, prostaglandins, blood pressure control

Normal pregnancy is associated with a decrease in the systemic pressor response to infused angiotensin II.[1-3] In contrast, women either with or destined to have pregnancy-induced hypertension are sensitive to this vasoconstrictor.[2, 3] Prostaglandins[4-6] and, more specifically, a balance between prostacyclin and thromboxane A_2 may be contributing factors in the control of vascular refractoriness to the pressor effects of infused angiotensin II.[7-9] Since thromboxane A_2 has potent vasoconstrictive and platelet aggregating actions and is released by circulating platelets,[10] platelet- and/or cyclooxygenase-inhibiting drugs have been used in recent clinical trials to prevent preeclampsia. Such therapy has been reported to be clinically beneficial.[11-13] For example, in a randomized placebo-controlled study Wallenburg et al.[12] used low-dose aspirin therapy in a group of angiotensin II–sensitive primigravid women and observed a decrease in the occurrence of proteinuric hypertension (preeclampsia). However, treatment failures have been reported in each of these studies.[11-13] Recently, Spitz et al.[14] reported that low-dose aspirin therapy (81 mg/day) dramatically increased the prostacyclin/thromboxane A_2 ratio in the plasma of angiotensin II pressor–sensitive women and that this was associated with partial restoration of angiotensin II pressor refractoriness in some (53%) but not all of these women; that is, we observed a heterogeneous angiotensin II pressor response after 1 week of low-dose aspirin therapy. Because of the small numbers of patients stratified into the various angiotensin II–sensitive and nonsensitive subpopulations after low-dose aspirin therapy, we did not report data regarding clinical outcome.[14]

Although we[14] and others[15, 16] have demonstrated that low-dose aspirin therapy results in decreased sensitivity to infused angiotensin II in most pregnant women, these infusions are time-consuming, are invasive, and have the theoretic risk of causing a hypertensive emergency in women who might be exquisitely pressor sensitive. Thus large clinical trials involving low-dose as-

pirin therapy are being conducted currently in unselected populations. In the present study we administered low-dose aspirin throughout the third trimester of pregnancy and after 1 week we evaluated the effect of such therapy on circulating eicosanoids and angiotensin II pressor responsiveness in both angiotensin II pressor–sensitive and nonsensitive women; we also correlated these responses with subsequent clincial outcome. The hypothesis tested was that women who were sensitive to infused angiotensin II and remained sensitive to this pressor agent during low-dose aspirin therapy would have significant decreases in prostacyclin and pregnancy-induced hypertension would develop subsequently.

Material and methods

In this study aspirin (81 mg) was administered daily throughout the third trimester of pregnancy to women who were not sensitive to the pressure effects of angiotensin II (normal; $n = 18$) and women who were sensitive (future hypertensive; $n = 22$). Sensitivity to angiotensin II was defined as a pressor dose < 10 ng/kg/min; refractoriness was defined as a pressor dose ≥ 10 ng/kg/min.[3, 14] After 1 week of therapy, we evaluated changes in (1) the minimum amount of angiotensin II per kilogram per minute required to increase diastolic blood pressure 20 mm Hg (the effective pressor dose of angiotensin II), (2) the concentrations of thromboxane A_2 measured as the stable metabolite thromboxane B_2 in serum and plasma, (3) the plasma prostacyclin measured as the stable metabolite 6-keto-prostaglandin $F_{1\alpha}$, and (4) plasma prostaglandin E_2. Angiotensin II pressor responses were measured in 18 nonsensitive women who served as controls; this was done to assess the effects of low-dose aspirin therapy on angiotensin II pressor responses, as well as circulating eicosanoids in normal pregnancies. The patients recruited for this study were nulliparous women from the antepartum clinics of Parkland Memorial Hospital, who were enrolled after exhibiting a positive rollover test. Some subjects also were recruited from women hospitalized with early-onset pregnancy-induced hypertension. In these women blood pressures had returned to normal ranges after being placed at bed rest. Candidates were excluded if they had a history of ingestion of any drugs other than iron supplementation or of chronic hypertension, heart disease, or diabetes. Prostaglandin data from 12 of the angiotensin II–sensitive women have been reported previously[14]; however, an additional aliquot of plasma and serum obtained from these women was assayed with the specimens obtained from the angiotensin II refractory women to decrease interassay variability. The women were included in the present study if they met these criteria: nulliparity, documented aspirin ingestion for the remainder of the pregnancy, and additional aliquots of blood that were available for prostaglandin assays. This study was approved by the institutional review board for human experimentation at The University of Texas Southwestern Medical Center.

The angiotensin II sensitivity test was performed as described previously.[3] Subjects were placed in the left lateral recumbent position in a quiet room. Blood pressure and heart rate were automatically measured from the right arm every 5 minutes with an automatic blood pressure cuff (Dinamap 1846 SX/P, Critikon, Inc., Johnson & Johnson, Tampa). After stabilization of the diastolic blood pressure for 15 minutes, an intravenous infusion was started in the left arm. Blood specimens for prostaglandin assays were collected as described below. After blood collection, the tubing was connected to an infusion pump with a syringe containing angiotensin II amide (1000 ng/ml in 0.9% sodium chloride, Ciba-Geigy Pharmaceuticals). The initial dose was 1 to 2 ng/kg/min; this was gradually increased at 5-minute intervals. The test was stopped after the diastolic blood pressure increased 20 mm Hg or if the dosage rate exceeded 40 ng/kg/min. After completion of the dose-response test and after blood pressures had returned to baseline values, the effective pressor dose of angiotensin II was infused again to confirm the pressure effect with that dose. The results in all studies were identical to the first pressor dose response.

After blood collection and the determination of angiotensin II sensitivity, the women were given a bottle of seven "baby" aspirin (81 mg) and instructed to take one aspirin daily for 1 week, at which time they were to return for a repeat examination. On return, pills were counted to confirm use. Those women in the hospital received aspirin as a daily medication. The procedures described above for blood collection and sensitivity to angiotensin II were repeated after 1 week of aspirin therapy. The women remained on daily low-dose apsirin therapy until the end of pregnancy. The remainder of pregnancy and labor and delivery were managed by obstetric house staff under the supervision of faculty not involved with this study. Clinical data regarding the outcome of the pregnancy, gestational age at delivery, Apgar scores, and birth weights were recorded. Pregnancy-induced hypertension was defined as the measurement of two diastolic blood pressures ≥ 90 mm Hg recorded at least 6 hours apart. Preeclampsia was defined as pregnancy-induced hypertension with the presence of proteinuria (at least 1+) on a voided urine specimen. Severe preeclampsia was defined as a diastolic blood pressure ≥ 110 mm Hg, and/or proteinuria (2+), and/or laboaratory evidence of end-organ damage.[17]

Prostaglandin assays. Serum concentrations of thromboxane B_2, which were reflective of platelet-derived thromboxane A_2, were obtained from blood samples after clotting (45 minutes at room tempera-

Patients are grouped according to pressor responses to angiotensin II. Values are means ± SD. Numbers in parentheses are numbers of observations. Means with different superscripts (a,b) are different ($p < 0.05$).

ture) and were used as an indication of therapy compliance. All patients had a fall in serum thromboxane B_2 levels of >60%. The assay for serum thromboxane B_2 has been described previously.[14] All samples were assayed in duplicate.

Blood samples (6.0 ml) for plasma prostanoids were obtained before initiation of the intravenous angiotensin II infusion, drawn into chilled syringes, transferred immediately to chilled tubes containing ethylenediaminetetraacetic acid (4.2 mg) and aspirin (0.3 mg), centrifuged at 5° C, and stored at −20° C until extraction, column chromatography, and radioimmunoassay. The method for measurement of plasma prostaglandins has been described and validated previously in our laboratory.[14]

Statistical analysis. All data are expressed as the mean ± 1 SD. Comparisons between groups were performed by the Student t test for paired and unpaired data or one-way analysis of variance, as appropriate. Nonparametric comparison between groups was performed by χ^2 or Fisher's exact test.

Results

Forty nulliparous women were enrolled and underwent angiotensin II infusions. Eighteen women were classified initially as nonsensitive (refractory) to angiotensin II whereas 22 women were sensitive to the angiotensin II infusion at the start of the study. These 22 women were further subdivided on the basis of the subsequent angiotensin II pressor response evaluated after 1 week of low-dose aspirin therapy. After 1 week of low-dose aspirin therapy, if the angiotensin II effective pressor dose equalled or exceeded 10 ng/kg/min, i.e., they became nonsensitive, they were grouped as angiotensin II–sensitive women responding favorably to aspirin therapy (sensitive-nonsensitive). There were 11 women in this group, five of whom had eicosanoid data reported previously.[14] After 1 week of low-dose aspirin therapy, if the angiotensin II sensitivity remained <10 ng/kg/min, they were classified as angiotensin II–sensitive women who were unresponsive to aspirin therapy (sensitive-sensitive). There were 11 women in this group, seven of whom had prostaglandin data reported previously.[14]

Listed in Table I are the clinical data for the three groups of pregnant women at the start of this study. All women were nulliparous and were of similar age and gestation at the start of the study. The angiotensin II–sensitive women who remained sensitive to the pressor effects of angiotensin II after 1 week of low-dose aspirin weighed 12 to 15 kg more than either of the other two groups ($p < 0.05$). Furthermore, the nonsensitive patients enrolled into this study had lower blood pressures and higher heart rates than the sensitive patients ($p < 0.05$). Women who became nonsensitive after 1 week of low-dose aspirin had an intermediate heart rate.

Platelet-derived serum thromboxane B_2 levels, an indicator of therapy compliance, fell markedly and similarly in all subjects in each group after 1 week of low-dose apsirin therapy [nonsensitive, 1084 ± 541 to 89 ± 63 pg/ml (92%); sensitive-nonsensitive, 1154 ± 746 to 79 ± 64 pg/ml (93%); sensitive-sensitive, 1655 ± 1780 to 196 ± 229 (88%) pg/ml; $p < 0.01$]. Plasma thromboxane B_2 and 6-keto-prostaglandin $F_{1\alpha}$, the stable metabolites of thromboxane A_2 and prostacyclin, respectively, as well as plasma prostaglandin E_2, also were measured. Before the start of aspirin therapy, the concentrations of each of these eicosanoids were similar in the three groups of patients subsequently stratified according to angiotensin II pressor sensitivity. The changes in these eicosanoids after 1 week of low-dose aspirin therapy are illustrated in Figs. 1, 2, and 3, respectively. Plasma thromboxane B_2 declined 61%, 60%, and 67% in the three study groups, respectively (Fig. 1). These changes in plasma and serum thromboxane A_2 levels after low-dose aspirin therapy were not significantly different among any of the three groups. Plasma 6-keto-prostaglandin $F_{1\alpha}$ levels were unchanged after 1 week of low-dose apsirin treatment in the non-

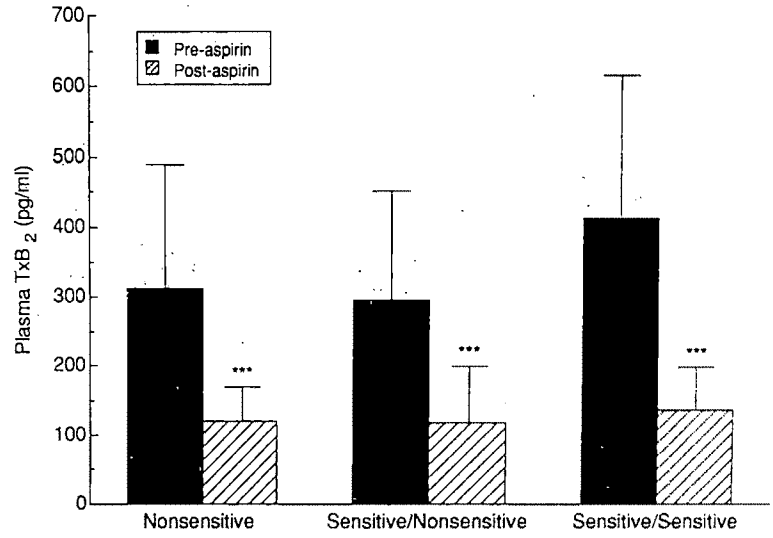

Fig. 1. Plasma concentrations of thromboxane B_2 in women who were sensitive or not sensitive to angiotensin II before and after low-dose aspirin therapy. *Triple asterisks,* $p < 0.001$ versus before aspirin.

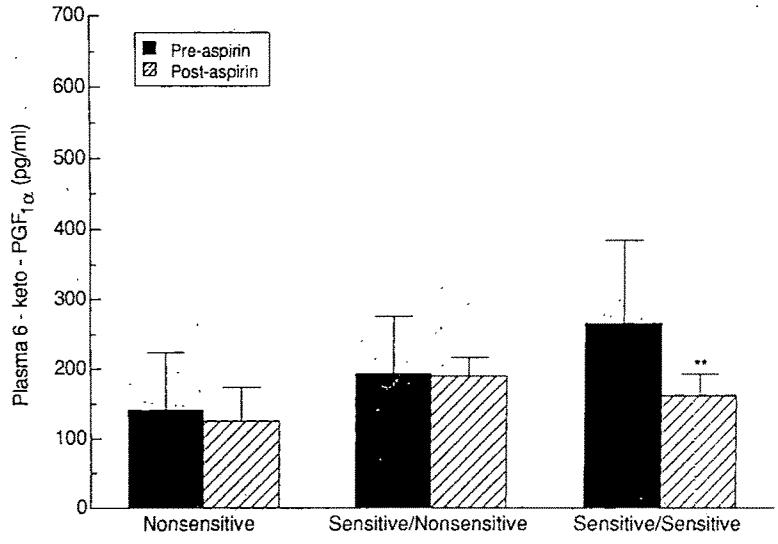

Fig. 2. Plasma concentrations of 6-keto-prostaglandin $F_{1\alpha}$ in women who were sensitive or not sensitive to angiotensin II before and after low-dose aspirin therapy. *Double asterisks,* $p = 0.016$ versus before asprin.

sensitive (142 ± 82 and 126 ± 47 pg/ml) and sensitive-nonsensitive (193 ± 82 and 189 ± 27 pg/ml) women; however, in the sensitive-sensitive group, plasma 6-keto-prostaglandin $F_{1\alpha}$ levels decreased 39%, from 264 ± 119 to 161 ± 31 pg/ml ($p < 0.05$; Fig. 2). As observed with the prostacyclin metabolite, prostaglandin E_2 also was unchanged in the nonsensitive and sensitive-nonsensitive study groups; however in the sensitive-sensitive women levels were reduced an average of 26% (476 ± 173 to 351 ± 111 pg/ml, $p < 0.038$) after 1 week of low-dose aspirin therapy (Fig. 3). One week of low-dose aspirin therapy increased the ratio of 6-keto-prostaglandin $F_{1\alpha}$/thromboxane B_2 in the nonsensitive (0.57 ± 0.24 to 1.23 ± 0.48), sensitive-nonsensitive (0.87 ± 0.65 to 3.47 ± 3.09), and sensitive-sensitive (0.3 ± 0.46 to 2.17 ± 2.98) patients ($p < 0.001$). This difference was greatest in the angiotensin II patients who became nonsensitive after 1 week of low-dose aspirin therapy.

The effective pressor dose of angiotensin II and clinical outcomes for all groups are shown in Fig. 4. The mean effective pressor dose of angiotensin

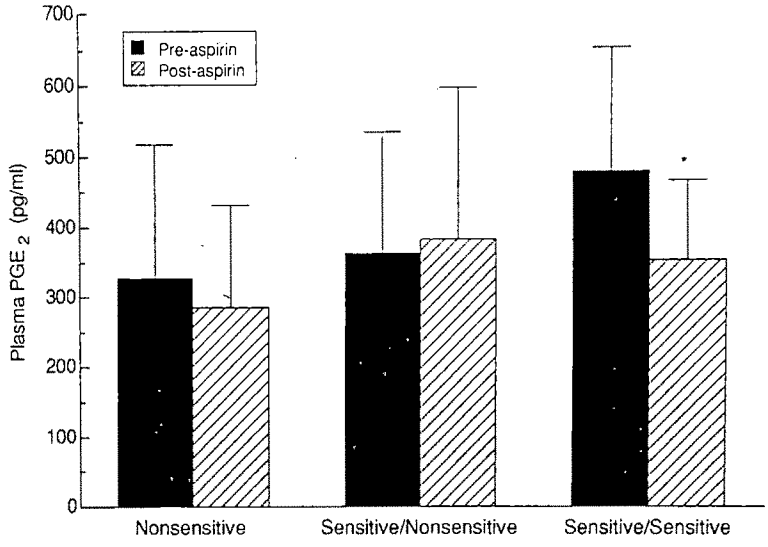

Fig. 3. Plasma concentrations of plasma prostaglandin E_2 in women who were sensitive or not sensitive to angiotensin II before and after low-dose aspirin therapy. *Asterisk*, $p < 0.038$ versus before aspirin.

II in the nonsensitive women was identical before and after 1 week of low-dose aspirin therapy (25.5 ± 10.6 and 25.5 = 10.6 ng/kg/min) (Fig. 4, *A*). Among these 18 patients, pregnancy-induced hypertension ultimately developed in seven (39%): four with mild disease (22%), two with preeclampsia (11%), and one with severe pregnancy-induced hypertension (6%). In the sensitive-nonsensitive group (Fig. 4, *B*), 6.3 ± 2.5 ng/kg/min was required initially to elicit the angiotensin II pressor response; 18.1 ± 7.9 ng/kg/min was required after aspirin therapy. Among these 11 patients, pregnancy-induced hypertension developed in four (36%): one with mild disease (9%), two with preeclampsia (18%), and one with severe pregnancy-induced hypertension (9%). In contrast, among the 11 women who were sensitive to the pressor effects of angiotensin II both before and after aspirin therapy (Fig. 4, *C*; 5.0 ± 2.5 and 4.7 ± 1.9 ng/kg/min, respectively) pregnancy-induced hypertension developed in all 11 women: four with mild disease (36%), two with preeclampsia (18%), and five with severe pregnancy-induced hypertension (45%). There was no difference in the occurrence of hypertension between the nonsensitive group (6/18) and the sensitive-nonsensitive group (4/11); however, there was a significant increase in the occurence of hypertensive complications in the sensitive-sensitive group (11/11) ($\chi^2 = 16.14$; $p < 0.001$) as compared with the other two groups.

Neonatal outcome data stratified by maternal angiotensin II pressor sensitivity are shown in Table II. There were no perinatal deaths and no birth weights below the 10th percentile for gestational age. Birth weights were lower among women who remained angiotensin II sensitive after aspirin therapy as compared with the other two groups ($p < 0.05$). The gestational age at delivery for women who were initially sensitive to angiotensin II was less than that of the nonsensitive women ($p < 0.05$).

We also evaluated whether the relationships described above for the serum and plasma eicosanoids in the three subpopulations of women also were observed when the data were stratified post hoc by the final clinical outcome (Table III). As expected, both serum and plasma thromboxane B_2 levels were decreased after 1 week of low-dose aspirin therapy in the patients who were normotensive and hypertensive at the end of gestation ($p < 0.01$). Although the plasma 6-keto-prostaglandin $F_{1\alpha}$ values were similar in the normotensive and hypertensive patients, aspirin decreased plasma 6-keto-prostaglandin $F_{1\alpha}$ concentrations 21% only in those women in whom hypertension subsequently developed ($p < 0.05$). The ratio of 6-keto-prostaglandin $F_{1\alpha}$/thromboxane B_2 was increased 181% and 198%, respectively in the normotensive and hypertensive study groups ($p < 0.01$). The decrease in prostacyclin metabolite was not specific since prostaglandin E_2 also was decreased by 25% only in the women who were subsequently diagnosed with hypertension ($p < 0.05$).

Comment

Low-dose aspirin therapy has been reported to decrease the occurrence of proteinuric hypertension and to have a beneficial effect on the clinical outcome in many but not all pregnancies.[11-13] It has been suggested that the control of normal vascular refractoriness to angiotensin II in pregnancy and the loss of this re-

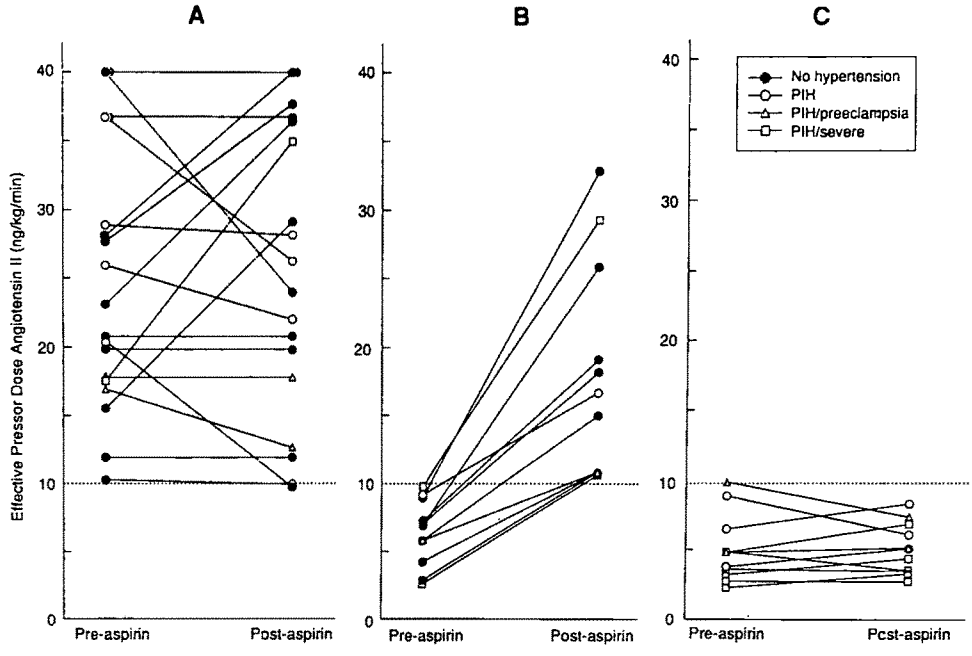

Fig. 4. Effective pressor dose and clinical outcome in women who were sensitive or not sensitive to angiotensin II before and after low-dose aspirin therapy. The occurrence of hypertension was **(A)** nonsensitive, 7 of 18; **(B)** sensitive-nonsensitive, 4 of 11; **(C)** sensitive-sensitive, 11 of 11 ($\chi^2 = 16.14$, $p < 0.001$).

fractoriness in women with pregnancy-induced hypertension may be the consequence of changes in the production of vascular prostaglandins[1-6] and, specifically, changes in the ratio of prostacyclin/thromboxane A_2.[9] In our initial report the effect of low-dose aspirin (81 mg/day) on the pressor response to angiotensin II was ascertained and related to levels of circulating eicosanoids.[14] The results of the present study are consistent with the view and are an extension of our prior observations,[14] with additional nulliparous patients, that there is a heterogeneity of pressor responses to infused angiotensin II during low-dose aspirin therapy. Moreover, unlike our previous study[14] we now present data that this heterogeneity is related to subsequent pregnancy outcome. In our previous report too few patients were studied either to evaluate pregnancy outcome or to stratify and report these data according to angiotensin II pressor sensitivity. One objective of the current study therefore was to expand the number of nulliparous women evaluated to determine clinical outcome. The second objective was to access the effect(s) of low-dose aspirin therapy in normal pregnant women who were refractory to angiotensin II, since there are clinical trials of low-dose aspirin therapy presently being conducted in large unselected populations.

The clinical outcome for nulliparous women who were initially sensitive to the pressor effects of angiotensin II and remained sensitive was not improved by low-dose aspirin treatment (Fig. 4, *C*). Specifically, 100% of the women who were sensitive to angiotensin II both before and after 1 week of low-dose aspirin subsequently had hypertensive complications. These women also had earlier delivery, and thus their neonates had lower birth weights. In addition to the differences in the pharamcologic and physiologic responses and clinical outcome of this subpopulation of women as compared with the two other groups, the eicosanoid responses to low-dose aspirin therapy also were different. As expected, plasma and serum thromboxane B_2 levels were inhibited in all three groups, demonstrating therapeutic compliance; however, only in the sensitive-sensitive group were both plasma 6-keto-prostaglandin $F_{1\alpha}$ and prostaglandin E_2 values also decreased. Inhibition of 6-keto-prostaglandin $F_{1\alpha}$ production has been reported by others.[13, 18] The observation that the prostacyclin metabolite and prostaglandin E_2 were decreased significantly only in the women who remained angiotensin II sensitive after 1 week of low-dose aspirin therapy might be explained by differences in the metabolic clearance rate and/or the apparent volume of distribution of the aspirin. However, our observation that plasma thromboxane B_2 was decreased to a similar extent in all three groups argues against the hypothesis that changes in the metabolic clearance rate might account for this phenomenon. Evidence against there being a difference in the apparent volume of distribution is obtained from the observation that, although the women in the sensitive-sensitive

treatment group weighed 18% to 23% more than those in the other two groups, the plasma thromboxane B_2 levels were decreased similarly, and only in the heavier group were there decreases in 6-keto-prostaglandin $F_{1\alpha}$ as well as prostaglandin E_2. An alternative hypothesis is that the cyclooxygenase enzyme sensitivity to aspirin of the women in the sensitive-sensitive group is greater than that in the other two groups. It is also possible that the ability of the tissues to synthesize new cyclooxygenase enzyme after the irreversible inhibition by aspirin is different in the women who remained sensitive to angiotensin II.

After 1 week of low-dose aspirin therapy, 50% of sensitive women became refractory to the pressor effects of infused angiotensin II, i.e., the sensitive-nonsensitive subgroup (Fig. 4, *B*). Although inhibition of serum and plasma thromboxane B_2 was similar in all three groups, plasma levels of 6-keto-prostaglandin $F_{1\alpha}$ and prostaglandin E_2 were unaltered after 1 week of low-dose aspirin. Furthermore, those angiotensin II–sensitive patients who became refractory to the pressor effects of angiotensin II after 1 week of low-dose aspirin therapy had improved clinical outcomes; that is, their pregnancies were less likely to be complicated by hypertension and they were delivered nearer to term. Although the occurrence of hypertension in this group, four of 11 (36%), was significantly less than that in the nonresponders (sensitive-sensitive), it was higher than expected from previous reports of similarly selected patients[12] or a population mixed with multiparous women.[13] The reason(s) for this is unclear but may be explained in part by the fact that low-dose aspirin therapy in the current study was instituted later in pregnancy in these women with positive rollover test results and in some women only after the onset of mild, transitory hypertension. Other factors such as the dose of aspirin (81 vs 60 mg),[12] population differences, a combination of the above, or as yet unidentified factors might also have contributed to this result.

There was one notable exception to the above, a 15-year-old Hispanic woman who had been admitted for in-hospital bed rest because of transient hypertension and subsequently left against medical advice. Blood pressure had normalized (107/56 mm Hg) before her first angiotensin II infusion; the effective pressor dose was 9.8 ng/kg/min at 31 weeks' gestation and increased to 29.2 ng/kg/min after 1 week of low-dose aspirin therapy. While in the hospital and receiving aspirin therapy, normal blood pressure readings were maintained. She left the hospital at 35 weeks' gestation and discontinued aspirin. She returned 15 days later in a postictal condition with a blood pressure of 170/120 mm Hg and proteinuria (2+). The diagnosis of eclampsia was made and she had one more seizure before delivery. The effect of discontinuing aspirin therapy on eicosanoid production and clinical outcome is unknown, and unfortunately blood specimens were not obtained after her return to the hospital.

A relatively high occurrence of hypertensive complications (39%) was observed among the women who

were outpatients without evidence of incipient hypertension. Although these women were enrolled in the study after a positive rollover test result, they were refractory to infused angiotensin II. Although there was no change in the effective pressor dose of angiotensin II among these women as a group (Fig, 4, *A*), those who became more sensitive to the pressor effects of angiotensin II after aspirin therapy but still required ≥10 ng/min/kg had an 80% occurrence (4/5) of hypertension. There was one exception worth noting. This woman had an effective pressor dose of angiotensin II that increased from 17.5 to 35 ng/kg/min after 1 week of low-dose apsirin; despite this increased refractoriness to infused angiotensin II, severe preeclamspia developed. It is unclear what differentiates these women from the others in this group. They may represent instances of noncompliance after the last study period. Since pregnancy-induced hypertension developed in seven of 18 (39%) initially nonsensitive patients, an observation not anticipated, it is possible that there may be some as yet undescribed adverse effects from low-dose aspirin treatment in normal gravid women. Nevertheless, this group of women did have significantly longer overall gestations than those initially sensitive to angiotensin II.

In addition to the prehoc stratification of the eicosanoid data on the basis of angiotensin II sensitivity, we also performed a post hoc stratification of the data on the basis of whether these women became hypertensive by the end of pregnancy (Table III). We observed similar relationships as noted earlier, i.e., both groups had similar and dramatic falls in serum and plasma thromboxane B_2 levels, confirming therapeutic compliance; however, only in those women in whom hypertension subsequently developed did significant decreases in 6-keto-prostaglandin $F_{1\alpha}$ (21%) and prostaglandin E_2 (25%) concentrations occur. The 6-keto-prostaglandin $F_{1\alpha}$/thromboxane B_2 ratio has been suggested to be an important factor in, or marker of, pregnancy-induced hypertension.[1-6, 9, 14] When we examined the changes in this ratio in the plasma of women in the three study groups on the basis of angiotensin II sensitivity before and during low-dose aspirin therapy, it was increased 116% in the nonsensitive, 299% in the sensitive-nonsensitive, and 171% in the sensitive-sensitive patients after 1 week of low-dose aspirin therapy. This rise was greatest in those women who became nonsensitive after 1 week of low-dose aspirin therapy whether they did or did not subsequently become hypertensive. However, the relative increase in the ratio after 1 week of low-dose aspirin therapy was similar when stratified according to the subsequent development of hypertension, i.e., normotensive (181%) or hypertensive (198%) (Table III). Thus this greater effect of low-dose aspirin therapy to increase this ratio in the sensitive-nonsensitive group appeared to occur concomitantly with the changes in the effective pressor dose of angiotensin II rather than as a predictor of the future hypertensive complications.

The relationship observed in this study among differences in vascular reactivity, different patterns of prostaglandin response to low-dose apsirin, and clinical outcome is suggestive of a related, underlying pathophysiologic phenomenon. An attractive single hypothesis is that a metabolic and/or an enzymatic defect renders some women incapable of maintaining an appropriate balance of factors that act to modulate vascular reactivity. Although prostaglandins may play a role in the pathogenesis of pregnancy-induced hypertension,[4, 19] other factors may work alone or in combination with prostaglandins to contribute to the maintenance of normal vascular reactivity. Metabolic or enzymatic defects are often genetically determined in an autosomal recessive manner, and several authors[20-22] have suggested that the predisposition for preeclampsia may reflect this type of defect. Whether the associations observed in this study are due to a single enzyme defect or a more complex situation remains to be ascertained. Our observations regarding low-dose aspirin therapy further support the concept that this agent is not "the answer" for the prevention of preeclampsia in all women, at least in the setting and dosage used in this study.

We thank Sheri Teriot, Lucy Dodd, Tammie Plumlee, and Stephanie Higgins for their technical assistance and the house officers in Obstetrics and Gynecology at Parkland Memorial Hospital for their assistance in the clinical management of the women described in this study. We also wish to thank Ciba-Geigy for their generous gift of the angiotensin II amide used in this investigation.

Maternal and uteroplacental hemodynamic effects of chronic captopril in the hypertensive, term-pregnant rat

William C. Mabie, MD, Robert A. Ahokas, PhD, and Baha M. Sibai, MD

Memphis, Tennessee

The chronic effects of captopril on maternal hemodynamics and organ perfusion were investigated in 10 untreated and 10 captopril-treated pregnant spontaneously hypertensive rats by means of the radioactive-labeled microsphere technique. The normal decrease in blood pressure during gestation was prevented by reduction of litter size to two conceptuses on day 7 of gestation. Captopril (≈10 mg/kg/day) or drug vehicle (50% ethyl alcohol) was administered intraperitoneally by an osmotic pump from day 7 to 21. At term mean arterial pressure was 23% lower in the captopril-treated group as the result of a 29% decrease in total peripheral resistance without a significant change in cardiac output. The decrease in total peripheral resistance was primarily caused by a decline in splanchnic and skin resistances. Maternal organ and uteroplacental perfusion were not significantly altered. We conclude that administration of captopril during the last 2 weeks of pregnancy in the hypertensive rat effectively lowers maternal blood pressure without adverse effects on organ and uteroplacental perfusion. (AM J OBSTET GYNECOL 1990;163:1861-7.)

In 1981 captopril was approved by the Food and Drug Administration for use as an antihypertensive agent in the United States.[1] Since then two other angiotensin-converting enzyme inhibitors, enalapril and lisinopril, have been approved and at least 14 other such inhibitors are under development.[2] Because of

their efficacy and low side-effect profile angiotensin-converting enzyme inhibitors are widely used as first-line therapy for hypertension.

The mechanism of action of the angiotensin-converting enzyme inhibitors is not completely understood, but it is thought that they induce vasodilatation by inhibiting angiotensin-converting enzyme, the enzyme that converts angiotensin I to angiotensin II. In addition to being a potent vasoconstrictor, angiotensin II stimulates aldosterone secretion and increases sympathetic outflow centrally. Because angiotensin-converting enzyme is identical to kininase II, which inactivates bradykinin, an additional antihypertensive effect may result from increased bradykinin levels. Finally, certain angiotensin-converting enzyme inhibitors increase synthesis of the vasodilating prostaglandins E_2 and I_2.[2-4] Accumulating evidence indicates that the major site of angiotensin II production is not in blood but in tissues (e.g., vascular, cardiac, renal, and brain). The decrease in blood pressure correlates better with the degree of inhibition of the vascular tissue renin-angiotensin system than with the circulating renin-angiotensin system.[2]

As with any antihypertensive drug, the primary concerns about the use of captopril in pregnancy are the possible adverse effects on placental perfusion and the risk of congenital malformations. Captopril caused fetal death in rabbits, apparently by reduction of uteroplacental perfusion.[5] It caused maternal and fetal hypotension and stillbirth in sheep.[6] Although results are conflicting, congenital malformations and other fetal complications have been associated with its use in human pregnancy.[7-9] Therefore it has been recommended that captopril not be used during pregnancy.[8, 10]

The spontaneously hypertensive rat is widely accepted as a model of human essential hypertension. However, even in this genetically hypertensive animal, pregnancy has a profound blood pressure–lowering effect. During the last week of gestation blood pressure progressively decreases and usually reaches normotensive levels by term. We have recently shown that the magnitude of the decrease in blood pressure in the pregnant spontaneously hypertensive rat is directly proportional to litter size.[11] The resistances of virtually all the maternal organ vascular beds, including the uterus and placentas, at term are inversely related to litter size. Thus reducing litter size to one or two conceptuses shortly after implantation prevents the normal decrease in blood pressure, producing a model of essential hypertension during pregnancy. The purpose of this study was to evaluate the effects of lowering maternal blood pressure with captopril during the last 2 weeks of pregnancy on maternal and uteroplacental hemodynamics at term in the hypertensive, pregnant rat.

Material and methods

This research conforms with the "Guiding Principles in the Care and Use of Laboratory Animals" approved by the Council of the American Physiological Society and with federal laws and regulations. The protocol used was approved by the University of Tennessee, Memphis, Animal Care and Use Committee.

Virgin female spontaneously hypertensive rats (10 to 12 weeks of age) were purchased from Harlan/Sprague-Dawley, Inc. (Indianapolis). They were housed four per cage in a temperature-controlled room (23° ± 1° C) with lights on from 7 AM to 7 PM and were fed Purina Laboratory Rodent Chow (Ralston Purina, St. Louis) as desired with tap water to drink. For breeding, the females were housed 1 : 1 with mature male spontaneously hypertensive rats. Vaginal smears were checked daily in the morning for the presence of spermatozoa. The day vaginal smears were sperm positive was designated day 0 of pregnancy and the timed pregnant rats were housed singly throughout pregnancy.

Systolic blood pressure was measured by tail-cuff plethysmography (IITC, Inc., Woodland Hills, Calif.) and was monitored every other day throughout gestation. For these measurements the rats were prewarmed to 30° C for 15 to 20 minutes in an incubator. They were then placed in a Plexiglas restraining cage and an inflatable cuff with a photoelectric sensor was placed around the base of the tail. The cuff was then inflated to a pressure of 250 mm Hg. The pressure was gradually released until a pulse was detected (systolic blood pressure). The mean of 3 to 5 determinations was recorded for each day.

On day 7 of gestation a laparotomy was performed with the rat under light methoxyflurane anesthesia and litter size was reduced to two (one in each uterine horn) by aspiration of embryos through small incisions in the antimesometrial uterine wall. The uterine incisions were then closed with sutures. A sterile osmotic minipump (model 2001, Alza Corp., Palo Alto, Calif.) filled with either a sterile solution of captopril (200 mg/ml) or drug vehicle (50% ethyl alcohol) was placed in the abdominal cavity to administer the contents intraperitoneally. Infusion rate was 0.5 μl/hr (2.4 mg of captopril per day). This rate of infusion resulted in a dosage of ~10 to 12 mg/kg/day. The abdominal incisions were closed, and the rats were injected with penicillin G (30,000 U/kg intramuscularly) and returned to their cages for the duration of pregnancy.

On postmating day 21 (the day before delivery), mean arterial pressure, cardiac output, and organ blood flows were measured with the radioactive-labeled microsphere technique described previously.[12-14] Mean arterial pressure, cardiac output, and organ blood flows

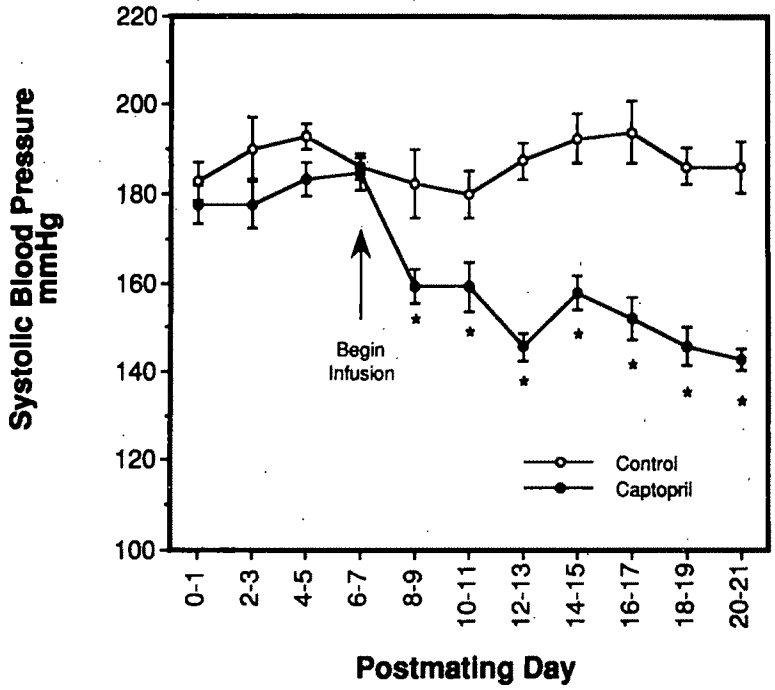

Fig. 1. Changes in systolic blood pressure during gestation in control and captopril-treated spontaneously hypertensive rats. Osmotic pump for intraperitoneal drug administration was implanted on day 7. Data are plotted as mean ± SEM. *Asterisk* indicates significant difference between groups ($p < 0.05$).

were measured after a minimum 2-hour anesthesia recovery period.

The data were expressed as the mean ± SEM. Systolic blood pressure data was analyzed by two-way analysis of variance. Student *t* test was used for comparison of mean arterial pressure, cardiac output, total peripheral resistance, organ flows, and organ vascular resistances between groups. The 95% confidence level was accepted as statistically significant for all analyses.

Results

Fig. 1 depicts the mean systolic blood pressure measured on alternate days during gestation for the untreated and captopril-treated rats. On day 0, mean systolic blood pressure in the two groups was not different. On day 7, the day treatment was started, mean systolic blood pressure was 186 ± 3 mm Hg and 185 ± 4 mm Hg in the untreated and captopril-treated groups, respectively. Captopril produced a significant reduction in mean systolic blood pressure that persisted throughout gestation beginning on the first day or two after pump implantation. On day 21, mean systolic blood pressure was 186 ± 6 mm Hg and 143 ± 2 mm Hg in the untreated and captopril-treated rats, respectively.

Table I shows the total body, maternal organ, and fetal and placental weights of the untreated and captopril-treated rats. Net maternal weight, but not mean fetal or placental weight, was significantly lower in the captopril-treated compared with the untreated rats. This was primarily a result of lower carcass, skin, and liver weights. Captopril treatment may have resulted in reduced food consumption, although this factor was not measured. Nine of the control rats had two fetuses at term compared with six of the captopril-treated rats, a nonsignificant difference. One rat in the control group and four in the captopril-treated group aborted one conceptus and carried one to term. There was no decaying tissue found in the uteri of the rats with only one fetus that would suggest recent fetal death, and all living fetuses appeared structurally normal. There was no significant difference in mean fetal or placental weight between the two groups.

The effects of captopril on maternal hemodynamics at term are summarized in Fig. 2. Mean arterial pressure was 23% lower in the captopril-treated group than in the control group (130.2 ± 4.7 mm Hg vs 169.0 ± 3.6 mm Hg, $p < 0.01$). Maternal cardiac index was unchanged but total peripheral resistance of the captopril-treated rats was 29% lower than that of the untreated rats (4.68 ± 0.38 vs 3.33 ± 0.30 mm Hg/ml/min/100/gm, $p < 0.02$).

There was a nearly significant increase ($p = 0.06$) in apparent lung blood flow (1.6 ± 0.3% vs 5.2 ± 1.8%

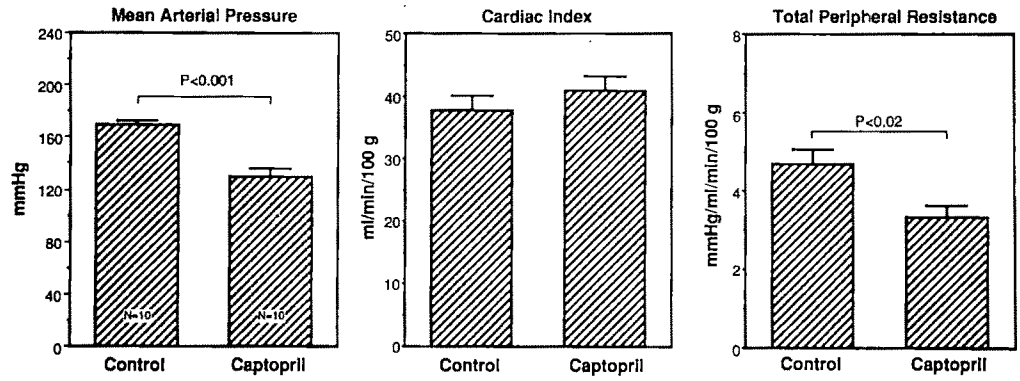

Fig. 2. Mean arterial pressure, cardiac index, and total peripheral resistance at term in 10 control and 10 captopril-treated (≈10 mg/kg/day) spontaneously hypertensive rats.

Table I. Total body, maternal organ, and fetal and placental weights of untreated and captopril-treated rats

	Control	*Captopril*	*Significance*
Total body weight, day 0 (gm)	197.2 ± 3.5	211.0 ± 7.0	
Total body weight, day 21 (gm)	251.2 ± 7.0	263.6 ± 5.0	$p \leq 0.10$
Net maternal weight, day 21 (gm)	207.8 ± 6.0	189.6 ± 3.5	$p \leq 0.02$
Carcass (gm)	142.33 ± 4.74	129.63 ± 2.49	$p \leq 0.05$
Skin (gm)	34.45 ± 0.92	32.09 ± 0.72	$p \leq 0.05$
Brain (gm)	1.82 ± 0.03	1.80 ± 0.03	
Heart (gm)	1.06 ± 0.04	0.95 ± 0.06	$p < 0.10$
Lungs (gm)	1.21 ± 0.04	1.17 ± 0.03	
Stomach (gm)	1.30 ± 0.05	1.25 ± 0.03	
Small intestine (gm)	4.95 ± 0.18	4.81 ± 0.19

Spleen (gm)	0.45 ± 0.18	0.48 ± 0.03	
Pancreas (gm)	0.67 ± 0.07	0.62 ± 0.05	
Kidneys (gm)	1.56 ± 0.17	1.53 ± 0.05	
Adrenal glands (gm)	0.08 ± 0.01	0.08 ± 0.01	
Ovaries (gm)	0.11 ± 0.01	0.11 ± 0.01	
Uterus (gm)	2.15 ± 0.12	1.71 ± 0.11	$p < 0.05$
Litter size	19/20	16/20	
Mean fetal weight (gm)	4.72 ± 0.22	4.65 ± 0.26	
Mean placental weight (gm)	0.58 ± 0.03	0.59 ± 0.09	

of cardiac output) in the untreated and captopril-treated groups, respectively. This may have been a result of the opening of systemic arteriovenous shunts by captopril.

Fig. 3 illustrates the splanchnic, skin, and remaining carcass blood flows and vascular resistances of untreated and captopril-treated rats. Captopril produced significant reductions in splanchnic and skin vascular resistances but had no significant affect on splanchnic, skin, or carcass blood flows.

Fig. 4 summarizes the cardiac, renal, adrenal, and reproductive organ blood flows and resistances in untreated and captopril-treated rats. There were no statistically significant differences between groups in either blood flow or resistance values.

Comment

The traditional concept of the renin-angiotensin system is that of a circulation-borne endocrine system in which angiotensinogen is produced by the liver, renin by the kidney, and angiotensin-converting enzyme by the lung. The product of this biochemical cascade, angiotensin II, acts on specific receptors in multiple target organs. However, recent data demonstrate that renin and angiotensin are synthesized locally in many tissues (e.g., blood vessels, heart, lungs, kidneys, adrenals, and brain). The emerging concept is that angiotensin II produced locally at vascular tissue sites by an endogenous renin-angiotensin system may play an important role in the tonic control of vascular resistance. This concept implies that local angiotensin II concentrations

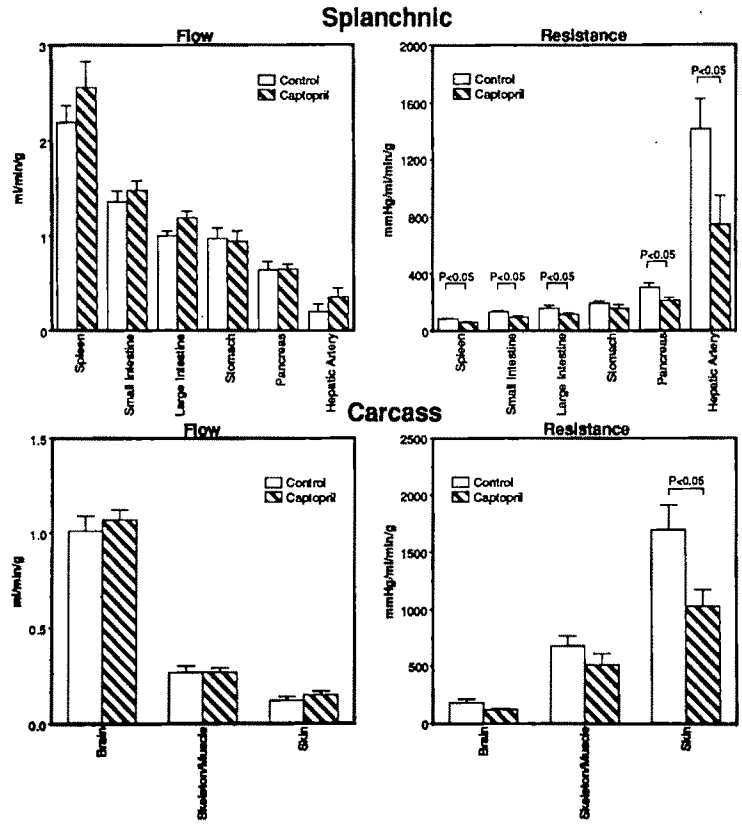

Fig. 3. Splanchnic and carcass blood flows and vascular resistances at term in 10 control and 10 captopril-treated spontaneously hypertensive rats.

may exceed plasma levels and helps to explain why angiotensin-converting enzyme inhibitors lower vascular resistance in normal and low renin hypertension, why nephrectomized rats continue to produce angiotensin II, and why the duration of antihypertensive response to angiotensin-converting enzyme inhibitors far exceeds the duration of serum angiotensin-converting enzyme inhibition.[3]

The results of this study show that chronic intraperitoneal captopril (~10 mg/kg/day) lowered blood pressure by decreasing total peripheral resistance without affecting cardiac output. The decrease in total peripheral resistance was primarily a result of a significant decline in splanchnic and skin resistances, although small decrements in resistance occurred in many other organs including the kidney, adrenal, uterus, placenta, ovary, skeletal muscle, and brain. Because blood flow did not increase significantly in any organ, perfusion pressure must have fallen in parallel with resistance.

These results differ from our previous studies of other antihypertensive drugs in the hypertensive, pregnant spontaneously hypertensive rat. Short-term administration of hydralazine and nifedipine produced generalized vasodilatation except in the skin and in many of the splanchnic organs.[12, 13] With labetalol the antihypertensive effect was primarily the result of a decline in cardiac output, but small decrements in resistance occurred in many regions except the carcass and splanchnic region.[14] Although specific reasons for the different regional vascular effects are not precisely known, they are probably related to the different mechanisms of drug action and to distribution of receptors blocked by the various drugs. The fact that captopril had a more pronounced effect on skin and splanchnic organ resistance suggests that these vascular beds may be more dependent on the renin-angiotensin system for regulation of their tone than other vascular beds in the body. However, the other vascular beds may also be constricted by increased sympathetic nervous activity as a result of a baroreflex compensatory response to the decrease in blood pressure induced by dilatation in the skin and splanchnic beds. In our experience, the skin and splanchnic regions receive 20% to 30% of total cardiac output in the conscious, term-pregnant spontaneously hypertensive rat (unpublished data). Sizable falls in resistance in these large vascular beds could

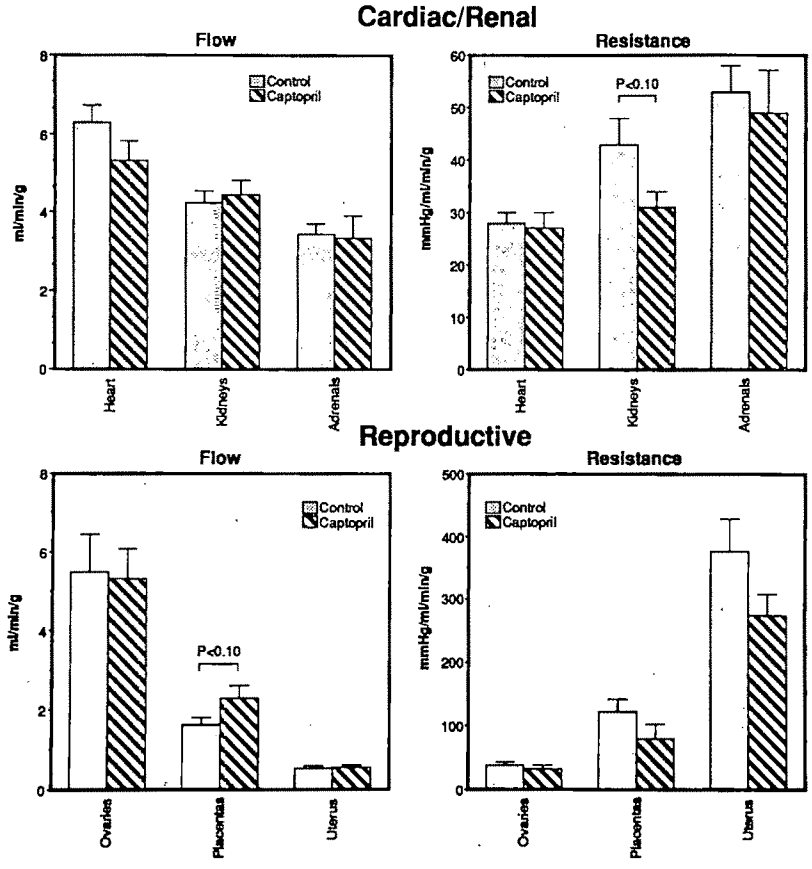

Fig. 4. Cardiac/renal and reproductive organ blood flows and resistances at term in 10 control and 10 captopril-treated spontaneously hypertensive rats.

conceivably reduce blood pressure enough to trigger baroreflex compensatory vasoconstriction, thus offsetting generalized vasodilatation produced by captopril.

Koike et al.[15] administered captopril orally once daily at doses of 10 mg/kg and 30 mg/kg for 6 weeks to male spontaneously hypertensive rats. The decrease in systolic blood pressure was less than that observed in our study even at the 30 mg/kg dose. By use of the radioactive-labeled microsphere technique, cardiac output was found to increase in a dose-dependent manner and reached statistical significance in the high-dose group, whereas total peripheral resistance decreased. Cerebral and renal blood flow increased dose-dependently, whereas flow to other organs was not significantly affected. Antonaccio et al.[16] reported that oral captopril (30 mg/kg) increased blood flow to all organs examined in spontaneously hypertensive rats, and the effect was statistically significant for the splanchnic area. We do not know why our results differ from these results, but it may be because of different routes of drug administration; because of constant, low-level exposure to captopril rather than bolus, high concentrations of the drug; or because we used pregnant female spontaneously hypertensive rats.

In this model use of captopril produced no adverse effect on uteroplacental blood flow. These findings are in contrast with the work of Ferris and Weir,[5] who noted in normotensive pregnant rabbits that acute captopril administration (5 mg/kg intravenously) reduced uterine and placental blood flow. They speculated that blockade of angiotensin II synthesis with a resultant decrease in uterine prostaglandin E_2 synthesis may have been the cause. In chronic studies with rabbits, captopril (2.5 or 5 mg subcutaneously daily) caused a marked decrease in fetal survival. Similarly, Broughton Pipkin et al.[6] found that administration of captopril (2.8 to 3.5 mg/kg intravenously) was associated with a much increased stillbirth rate in both sheep and rabbits; however, enalapril (1 or 2 mg/kg intravenously), which apparently does not cross the sheep placenta, was associated with a lower stillbirth rate.[17] The loss of four conceptuses in our captopril-treated group compared with only one conceptus in the control group, although not statistically significant, is at least consonant with the observations made in rabbits and sheep that use of captopril is associated with increased pregnancy wastage. The loss of conceptuses in both groups of rats apparently occurred early in gestation and was probably re-

lated to surgical manipulation of the uterus because there was no decaying tissue or other evidence of a second pregnancy found in any of the rats with a single fetus. Our previous experience[11] has been that manipulation of the uterus to adjust litter size occasionally causes one or more of the adjacent conceptuses to abort. The fact that the remaining pups were normal in weight and development supports this explanation. If captopril had induced uterine ischemia, the surviving fetus and placenta would be expected to be growth retarded. This does not conclusively rule out the possibility that captopril caused the abortions, and further study is needed in this area.

In human pregnancy angiotensin-converting enzyme inhibitor therapy has been associated with several fetal and maternal complications including hypotension, growth retardation, oligohydramnios, anuria, renal failure, congenital malformations, stillbirth, and neonatal death.[8-10] However, more favorable results have been reported. Coen et al.[18] treated a patient with chronic glomerulonephritis throughout a twin pregnancy with a combination of captopril, hydralazine, and metoprolol. At term she was delivered of growth-retarded twins whose subsequent course to 10 months of age was unremarkable. Mochizuki et al.[19] reported good results with captopril as part of combination therapy in late pregnancy in three patients. Kreft-Jais et al.[20] reported the results of a French survey of pregnancies exposed to angiotensin-converting enzyme inhibitors between June 1985 and December 1986. Twenty-two women received captopril and nine received enalapril. Most women had renal disease or chronic essential hypertension. Two stillbirths occurred in the captopril group and one in the enalapril group. Preterm delivery occurred in 11 women who were given captopril and in one given enalapril. Six of 26 live-born babies were growth retarded.

In conclusion, chronic administration of captopril lowered blood pressure in the pregnant, hypertensive rat by decreasing total peripheral resistance without affecting cardiac output. Uteroplacental perfusion was unchanged, and no fetal growth retardation or congenital anomalies were noted. Nevertheless, because of conflicting animal data, potential risks to the fetus, and the availability of alternate drugs, the use of captopril in pregnant women should be avoided until further animal studies and human drug trials prove its safety.

We thank Ed B. Cannon for his laboratory technical assistance.

Induction of labor with pulsatile oxytocin

Karen C. Cummiskey, MD,[a] and M. Yusoff Dawood, MD[b]
Louisville, Kentucky, and Houston, Texas

In a prospective, randomized study, 106 patients underwent induction of labor with either pulsed (every 8 minutes) (n = 50) or continuous (n = 56) intravenous infusion of oxytocin. Maternal characteristics, gestational age at induction, induction-delivery interval, analgesia for labor, cesarean section rates, and newborn characteristics were similar in both groups. The mean ± SEM total oxytocin administered was significantly less in the pulsed group (3564 ± 487 mU) than in the continuous group (7684 ± 844 mU; $p < 0.0001$); the average dose of oxytocin administered per minute was significantly lower in the pulsed group (3.9 ± 0.3 mU/min) than in the continuous group (7.8 ± 0.4 mU/min; $p < 0.0001$); the peak or highest administered dose of oxytocin expressed per minute was also significantly lower in the pulsed group (9.6 ± 0.8 mU/min) than in the continuous group (14.1 ± 0.7 mU/min; $p < 0.0001$). These significant differences persisted even when controlled for parity, Bishop's score of the cervix, and number of days induction of labor was carried out. Uterine hyperstimulation occurred infrequently in both groups (3.6% to 4.0%). The pulsed group required a significantly smaller infusion volume (25 ± 14 ml) than the continuous group (780 ± 84 ml; $p < 0.0001$). Thus pulsatile administration uses significantly less oxytocin and infusion fluid but is as effective and safe as continuous infusion. (Am J Obstet Gynecol 1990;163:1868-74.)

Key words: Induction of labor, oxytocin, pulsatile oxytocin

Continuous intravenous administration of oxytocin is routinely used for induction and augmentation of labor.[1, 2] Use of oxytocin has been associated with increased maternal and fetal morbidity including uterine hyperstimulation and rupture, fetal distress with hypoxia, and an increased incidence of neonatal hyperbilirubinemia. These side effects appear to be primarily dose-dependent. With the increased utilization of intrauterine pressure monitoring and continuous fetal heart rate surveillance, these events are less common but remain potential concerns.

Endogenous oxytocin is secreted in spurts or pulses during spontaneous labor.[3] Because oxytocin binds to its myometrial receptors, causing the occupied sites to be temporarily unavailable to more continuously infused oxytocin, administration of oxytocin in pulses similar to its endogenous pulsatile secretion would appear to be a more physiologic regimen for induction of labor. Pavlou et al.[4] showed that pulsed administration of oxytocin was as effective as continuous intravenous infusion and required less oxytocin. In a recent pilot study on 20 patients, our group[5] found that pulsed administration of oxytocin for induction of labor not only was as effective as the continuous infusion but also used lower total and peak doses of oxytocin and produced a significantly lower incidence of hyperstimulation.

To further evaluate pulsatile administration of oxytocin for induction of labor, we conducted another prospective, randomized study in a larger number of patients to compare the efficacy and safety of pulsatile intravenous administration of oxytocin with the standard continuous intravenous administration of oxytocin. The patients in the pilot study reported by us[5] were not included in this analysis. This larger study would permit controlling for parity, Bishop's score, and number of days induction was performed when the two methods of giving oxytocin are compared. The results of this study are described in this paper.

Material and methods

Patient selection. One hundred six pregnant patients who required induction of labor for medical indications agreed to participate in this prospective, randomized study that was approved by the Institutional Review Board and was conducted at the University of Illinois Hospital, Chicago. Each patient gave informed consent before admission into the study and initiation of oxytocin administration. Randomization was carried out

Table I. Clinical characteristics of patients undergoing induction of labor with either pulsed or continuous oxytocin infusion

Maternal characteristic	*Pulsed oxytocin group (n = 50)*	*Continuous oxytocin group (n = 56)*	*Differences between treatment groups*
Age (yr) (mean ± SEM)	23.9 ± 0.8	23.4 ± 0.7	NS
Gravidity (mean ± SEM)	3.1 ± 0.3	2.4 ± 0.2	NS
Primigravid (No.)	21	31	
Multigravid (No.)	29	25	
Parity	1.3 ± 0.2	1.0 ± 0.2	NS
Gestational age (wk) (mean ± SEM)	39.1 ± 0.4	39.0 ± 0.3	NS
Bishop score			
Mean ± SEM	5.4 ± 0.4	5.4 ± 0.3	NS
Range	1-10	1-10	

by our pharmacy staff who assigned the patient to either group on the basis of a previously prepared randomization list. The need for induction of labor was determined by our obstetric staff. Women with a clinically contracted pelvis, previous cesarean sections, or fetal malpresentation were excluded. Fifty women were randomized to the pulsed infusion group and 56 to the continuous infusion group.

Administration of oxytocin. For pulsed administration of oxytocin, a 10-second pulse of oxytocin was delivered intravenously every 8 minutes with an Autosyringe AS-2C pump (Autosyringe, Hooksett, N.H.). The starting dose was 1 mU per pulse and the dose was doubled every 24 minutes (i.e., after three pulses of the same dose) until 32 mU per pulse. Thereafter the dose of oxytocin was increased by 8 mU per pulse until adequate uterine activity was achieved. To enable a wide range of doses available for use, the oxytocin was made up in two different concentrations of 100 or 800 mU/ml placed in a 5 ml syringe. The higher oxytocin concentration was used when a pulse dose of ≥32 mU per pulse was needed.

For continuous infusion oxytocin was given intravenously and continuously by an IMED 927 pump (Imed Corporation, San Diego). Starting with a dose of 1 mU/min, the oxytocin infusion was increased by 1 mU/min every 30 minutes until adequate uterine activity was achieved. Adequate uterine activity was defined as 160 montevideo units or more.

All cases were managed during induction of labor and delivery by our obstetric residents and faculty who also performed all the pelvic examinations. All patients had continuous electronic monitoring of fetal heart rate and uterine contractions. When uterine contractions were established, the patient underwent artificial rupture of the membranes if the cervix was dilated ≥3 cm. All monitor tracings were reviewed by one of us. Criteria for adequate labor, dysfunctional labor, and hyperstimulation were defined before the initiation of this study. Adequate (normal) labor was considered to be uterine activity demonstrating three or more uterine contractions in a 10-minute period with 160 montevideo units or more. Dysfunctional labor patterns were defined as coupling or tripling of uterine contractions for a total of ≥1 hour during induction of labor. Hyperstimulation was present if five or more uterine contractions were noted in succession without return to baseline tonus or a prolonged uterine contraction causing fetal bradycardia. Either of these two conditions required temporary cessation of oxytocin administration.

Statistical analysis. The means ± SEMs between the pulsed and continuous oxytocin infusion groups were analyzed for differences by means of χ^2 analysis, nonpaired Student's t test, and one-way analysis of variance. Two-tailed p values were used, and values >0.05 were considered not significant.

Results

The indications for induction of labor were similar in both groups. These included postdates, hypertension, preeclampsia, diabetes, intrauterine growth retardation, and premature rupture of membranes. In the pulsed group 30 patients required 1 day of attempted induction, 16 required 2 days, and 4 required 3 days. In the continuous group 35 women were delivered after 1 day of induction, 12 after 2 days, and 9 after 3 days.

The clinical characteristics of the patients are summarized in Table I. There were no significant differences with regard to maternal age, gravidity, gestational age, or Bishop scores at the time of induction. Table II summarizes the events during labor. The induction-to-delivery time, as reflected by the length of time the patient received oxytocin, was similar in the two groups. Use of pain medications and epidural anesthesia was not significantly different. Both groups had a low incidence of uterine hyperstimulation—4% in the pulsed group and 3.6% in the continuous group. Nevertheless, the pulsed group used a significantly smaller volume of fluid (25 ± 14 ml) than the continuous group (780 ± 84 ml) to deliver the oxytocin ($p < 0.0001$).

Table II. Labor characteristic of patients undergoing induction of labor with either pulsed or continuous oxytocin infusion

Labor characteristic	*Pulsed oxytocin group (n = 50)*	*Continuous oxytocin group (n = 50)*	*Difference between treatment groups*
Total time oxytocin given (min) (mean ± SEM)	846 ± 68	930 ± 74	NS
Total fluid received with infusion (ml) (mean ± SEM)	25 ± 13	780 ± 85	$p < 0.0001$
Pain medication (%)	52	41	NS
Epidural anesthesia (%)	14	29	NS
Contraction pattern (%)			
Normal	88	87.5	NS
Dysfunctional	8	8.9	NS
Hyperstimulation	4	3.6	NS

Table III. Characteristics of newborns delivered of patients undergoing induction of labor with either pulsed or continuous oxytocin infusion

Newborn characteristic	*Pulsed oxytocin group (n = 50)*	*Continuous oxytocin group (n = 56)*	*Difference between treatment groups*
Birth weight (gm) (mean ± SEM)	3185 ± 98	3255 ± 93	NS
Apgar score at 1 min			
Mean ± SEM	7.7 ± 0.2	7.8 ± 0.1	NS
Range	3-9	5-9	
<7 (No.)	6	6	
APGAR score at 5 min			
Mean ± SEM	8.6 ± 0.1	8.8 ± 0.1	NS
Range	5-9	7-10	
<7 (No.)	1	0	
Arterial cord blood pH (mean ± SEM)	7.30 ± 0.02	7.29 ± 0.02	NS
	(n = 14*)	(n = 14)	
Hyperbilirubinemia (No.)	3	5	NS
	(n = 26)	(n = 31)	

*Numbers studied for arterial cord pH and for neonatal serum bilirubin are shown in parentheses.

Forty-seven women (94%) in the pulsed group were delivered vaginally, with 3 (6%) requiring cesarean section, while 7 of the 49 (12.5%) in the continuous group were delivered by cesarean section. The indications for cesarean section were similar in both groups.

Relevant findings of the newborns are summarized in Table III. There were no differences between the two groups with regard to birth weight or Apgar scores at 1 and 5 minutes. Arterial cord pH determined in 14 patients from each group showed no significant differences. Of those infants screened independently by the pediatricians for hyperbilirubinemia in the newborn period, three infants were identified in the pulsed group and five infants in the continuous group. Although these numbers are not significantly different, when analyzed further, all three infants with hyperbilirubinemia in the pulsed group had a mean gestational age of 35 ± 1.0 weeks and a mean birth weight of 1953 ± 116 gm. The maximum serum bilirubin level was 11.7 ± 0.5 mg/dl. In contrast, the hyperbilirubinemic infants in the continuous group had a mean gestational age of 37.4 ± 1.2 weeks with a significantly higher mean birth weight of 3830 ± 184 gm ($p < 0.01$) and a significantly higher maximum serum bilirubin of 15.1 ± 0.7 mg/dl ($p < 0.001$).

Fig. 1 shows the mean ± SEM total dose of oxytocin administered during induction of labor for each group. The pulsed group used significantly less oxytocin with a mean total dose of 3564 ± 487 mU while the continuous group used 7684 ± 844 mU ($p < 0.0001$). To control for the number of days required for induction, the total dose of oxytocin was further evaluated according to the number of days labor was induced, as shown in Fig. 2. The pulsed group continued to demonstrate a significantly lower total oxytocin requirement than the continuous group regardless of the number of days of induction. To determine and control for the possible influence of the Bishop score of the cervix on

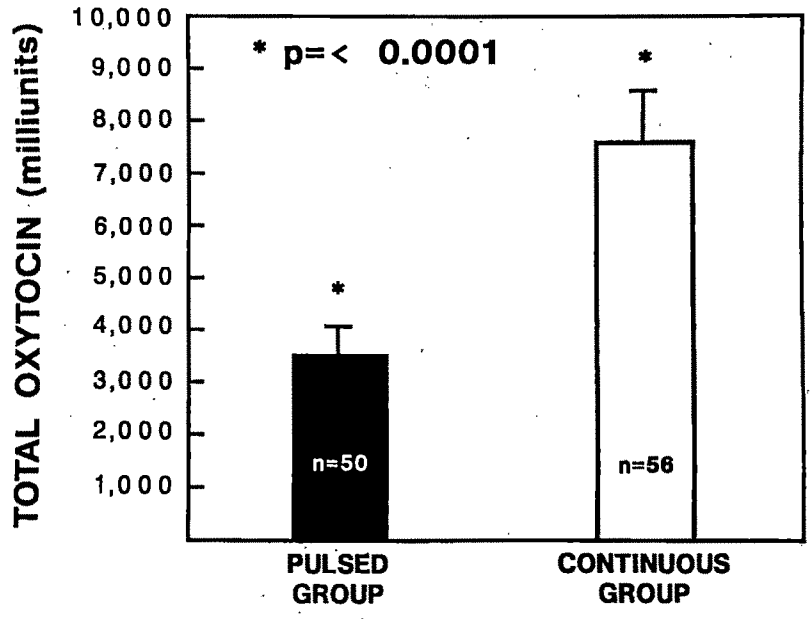

Fig. 1. Total dose of oxytocin (mean ± SEM) in patients receiving pulsed oxytocin compared with continuous oxytocin for induction of labor. The pulsed group received a significantly lower mean total dose of oxytocin as compared with the continuous group.

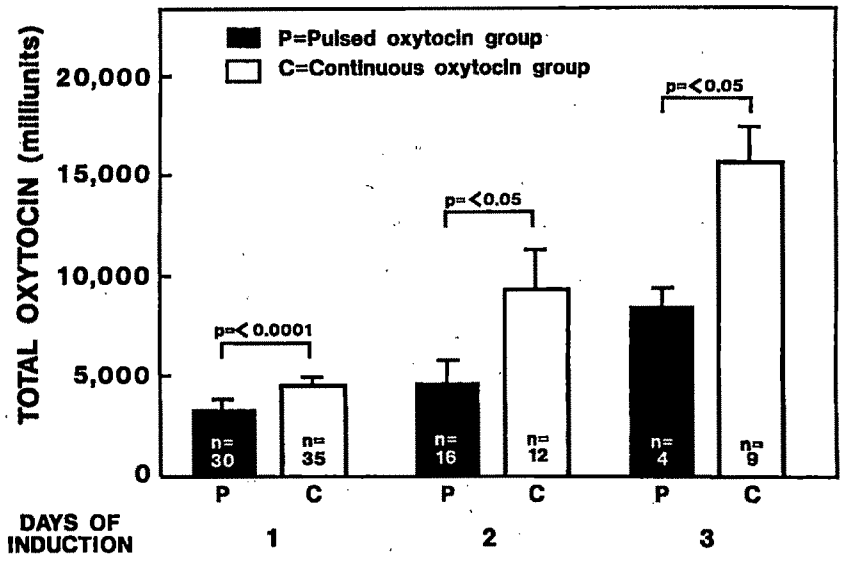

Fig. 2. Total dose of oxytocin (mean ± SEM) in patients receiving pulsed oxytocin compared with continuous oxytocin grouped according to the number of days of attempted induction of labor. The pulsed group always required significantly less oxytocin than the continuous group.

the total dose of oxytocin required for induction, the total dose of oxytocin required was reanalyzed for patients with low (0 to 4), moderate (5 to 8), and high (9 to 13) Bishop scores (Fig. 3). Within each of these three categories, the pulsed group consistently required significantly less total oxytocin than the continuous group ($p < 0.5$).

When the mean ± SEM doses of oxytocin in milliunits per minute for the two methods of giving oxytocin were compared, the pulsed group again had a significantly lower mean dose (3.9 ± 0.3 mU/min) than the continuous group (7.8 ± 0.4 mU/min; $p < 0.0001$). The mean dose of oxytocin per minute continued to be significantly lower with pulsed administration than with continuous administration when controlled for the number of days of induction and

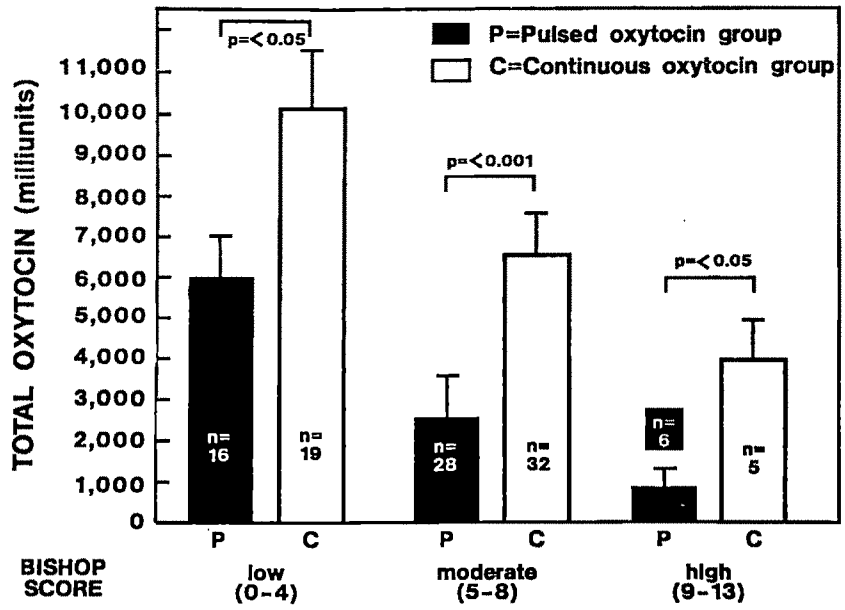

Fig. 3. Total dose of oxytocin (mean ± SEM) in patients receiving pulsed oxytocin compared with continuous oxytocin grouped according to the Bishop cervical scores of the patients. Irrespective of group according to Bishop scores, significantly less oxytocin was always used for pulsed administration than for continuous administration. Note that there was a more dramatic progressive drop in the total dose of oxytocin with pulsed administration as the Bishop scores progressed from low to moderate to high.

for low, moderate, and high Bishop scores (data not shown).

The highest or peak dose of oxytocin amortized per minute was also evaluated. The pulsed group had a lower peak dose of oxytocin (9.5 ± 0.8 mU/min) when compared with the continuous group (14.1 ± 0.7 mU/min; $p < 0.0001$). Again, the difference remained significant when controlled for the number of days of induction and for Bishop scores.

To remove the potential confounding influence that patients requiring cesarean section may have on those who are delivered vaginally with each method of administering oxytocin, the data on oxytocin for each group were reanalyzed only for those patients who achieved vaginal delivery but are not shown in the figures. The total dose of oxytocin remained significantly lower for the pulsed group (3218 ± 408 mU; $n = 47$) than for the continuous group (6985 ± 778 mU; $n = 49$; $p < 0.0001$). Likewise, the mean dose and the peak dose of oxytocin were significantly lower in the pulsed group (3.7 ± 0.3 and 9.3 ± 0.8 mU/min, respectively) than in the continuous group (7.6 ± 0.4 and 13.8 ± 0.8 mU/min, respectively; $p < 0.0001$ for both).

Comment

Our results demonstrate that pulsatile administration of oxytocin is as safe and as effective as continuous oxytocin infusion for induction of labor. Previous studies on induction of labor in smaller numbers of patients and on augmentation of labor found significantly less oxytocin was required when given by pulsatile administration than by continuous administration.[1-6] This study confirmed those previous reports demonstrating a lower total dose and mean and peak doses (expressed per minute) of oxytocin for induction of labor with pulsed oxytocin administration. The significant reduction in the dose of oxytocin required to induce labor with pulsed oxytocin persisted even when controlled for the number of days of attempted induction, the Bishop scores of the cervix, and the number of cesarean sections. Although we have recently also found that less oxytocin was requird to *augment* labor, the oxytocin needs for induction of labor are not similar to the requirements for augmentation. Because the number of patients in the present induction study is larger than in our preliminary study,[5] we are able to demonstrate a clear correlation between the total amount of oxytocin required and cervical ripeness (as reflected by the Bishop score) with both methods of oxytocin administration. The inverse relationship between the total dose of oxytocin required and the Bishop score was more acute with pulsed administration than with continuous administration of oxytocin.

Several basic and practical considerations predicated

our choice of the pulse frequency for administering pulsatile oxytocin and for the interval between dose increments. Endogenous oxytocin is released in frequent pulses or spurts during pregnancy and labor in women.[3, 7] Dawood et al.[3] have shown that during normal spontaneous labor, maternal plasma oxytocin levels show two to three pulses every 10 minutes.[8] Pharmacokinetic studies of oxytocin gave a half-life of 10 minutes and a metabolic clearance rate that was similar in both pregnant and nonpregnant subjects.[9] On the basis of the pulse frequency and pharmacokinetics of oxytocin and for convenience of adjusting the Autosyringe pump, we chose a pulse frequency of every 8 minutes for administration of the oxytocin. Seitchik and Castillo[10] have emphasized that the dose increment and the rate at which the dose is increased are critical determinants of both the maximum dose and the frequency of hypercontractility and/or fetal distress. Previous studies of constant intravenous infusion of oxytocin found that the minimum time required to reach a steady-state circulating level of oxytocin ranged from 20 to 40 minutes.[8, 11] An intermediate interval of 30 minutes was used before the dose of oxytocin was increased stepwise.

The action of oxytocin on the uterus is brought about through specific receptors that have been identified in the cell membranes of the smooth muscles of the uterus. The number of oxytocin receptors increases as gestation progresses. When these receptors are bound by oxytocin, they are no longer available, albeit temporarily, to more circulating oxytocin. Whereas the duration of oxytocin-receptor occupancy by oxytocin is not known, continuous infusion of oxytocin can be expected to rapidly saturate the uterine oxytocin receptors, thus giving rise to more circulating oxytocin than can be used by the uterus. Pulsed administration of oxytocin, which is similar to its endogenous release, is therefore a more physiologic method for giving oxytocin to stimulate uterine contractions.

The total dose of oxytocin required to establish contractions and maintain labor was significantly less with pulsed administration than with the continuous infusion. Because most complications of oxytocin are dose-related, reduction in the total dose will allow an even wider margin of safety. In a preliminary study we have previously demonstrated a significantly lower incidence of hyperstimulation with the pulsed administration of oxytocin for induction of labor.[5] In this study, involving a much larger number of patients, the incidence of hyperstimulation was low in both groups.

The risk of neonatal hyperbilirubinemia is dependent on both the total dose of oxytocin given to the mother and the maturity of the fetus.[12-14] In in vitro experiments, oxytocin increases osmotic swelling and deformability of erythrocytes in a time- and dose-dependent manner to bring about hemolysis, an effect similar to that of vasopressin.[15] An increased osmotic fragility of the erythrocytes associated with transplacental hyponatremia and its accompanying hypoosmolality has been found in neonatal hyperbilirubinemia related to oxytocin given to the mother.[14, 16] Singhi and Singh[15, 16] concluded that the transplacental passage of oxytocin administered to the mother could be responsible for the significant lowering of the cord sodium level and osmolality found with an oxytocin infusion >16 mU/min compared with a lower dose. Buchan[14] found an increased incidence of neonatal hyperbilirubinemia when mothers were given a mean total oxytocin dose of ≥4500 mU. Therefore pulsed administration of oxytocin with a mean total dose of 3200 to 3600 mU as found in this study should afford a wider margin of safety, especially for risk of oxytocin-associated neonatal hyperbilirubinemia, when compared with the higher mean total dose of 7000 to 7700 mU in the continuous infusion group. Three infants in the pulsed oxytocin group and five in the continuous oxytocin group developed clinically recognizable and biochemically confirmed neonatal hyperbilirubinemia. While these numbers are small, it is particularly noteworthy that all three infants with hyperbilirubinemia in the pulsed oxytocin group were preterm with low birth weights and comparatively lower maximum levels of serum bilirubin before therapy. None of the term infants in the pulsed group had hyperbilirubinemia. In contrast, the five infants in the continuous infusion group were more advanced in gestation, were heavier in birth weight, and had higher maximum levels of serum bilirubin. In addition to the dose of oxytocin, the maturity and size of the fetus are important variables in the risk of development of neonatal hyperbilirubinemia; therefore a larger number of patients will have to be studied so that the variability in weight and maturity of the newborn can be adequately controlled while the effect of the total dose of oxytocin on the risk of neonatal hyperbilirubinemia is examined.

Requiring a significantly smaller amount of infusion fluid to administer the oxytocin, pulsed administration may be advantageous in high-risk conditions requiring close monitoring or restriction of fluids such as in women with severe preeclampsia, pulmonary edema, or cardiac and renal diseases.

In conclusion, we found that pulsed administration of oxytocin is as safe and effective as continuous infusion, requires significantly less oxytocin with a wider margin of safety, and may be a more physiologic oxytocin regimen for induction and augmentation of labor. Further studies are indicated to determine the optimal pulse intervals and rates of increase of oxytocin when

Inhibition of spontaneous uterine contractions during the last trimester in pregnant baboons by an oxytocin antagonist

Laird Wilson, Jr., PhD,[a] Michael T. Parsons, MD,[b] and George Flouret, PhD[c]
Chicago, Illinois, and Tampa, Florida

The effect of a potent oxytocin antagonist, produced in our laboratories, on spontaneous uterine contractions in the pregnant baboon was examined. Three types of uterine contractions were studied: immediately after operation, during the nocturnal period, and near or at labor. Bolus intravenous injections of oxytocin antagonist were given and uterine activity was examined ±1 hour after the injection. The oxytocin antagonist caused a precipitate decrease (approximately 70%) in contractile force (mean amplitude × frequency) in the first 15 minutes after injection ($p < 0.05$); this force diminished to approximately 90% at the end of 1 hour for both nocturnal and labor contractions. In contrast, uterine contractions immediately after operation were diminished by only 60% within 60 minutes after the oxytocin antagonist. These results indicate that the oxytocin antagonist is a potent inhibitor and suggest that oxytocin is a primary regulator of spontaneous nocturnal and labor uterine contractions in the pregnant baboon. (AM J OBSTET GYNECOL 1990;163:1875-82.)

Key words: Oxytocin antagonist, pregnancy, tocolytic, preterm labor, baboon

The mechanism of parturition in the primate is poorly understood. A number of factors have been implicated in either the initiation or the progress of labor, including oxytocin,[1] prostaglandins,[2] leukotrienes,[3] and the ratio of estrogen to progesterone.[4] The role of oxytocin in initiation of labor is ambiguous because of the contradictory reports in the literature as to the correlation of oxytocin levels in the plasma of humans and nonhuman primates with advancing gestational age and labor.[5-8] The clinical importance of understanding the initiation and progress of labor is to apply this knowledge to control preterm labor, a major cause of fetal mortality and morbidity in obstetric medicine.

We have recently reported the development of a potent oxytocin antagonist that inhibits in vitro uterine contractions in response to oxytocin in tissue from rats, baboons, and humans,[9] inhibits in vivo contractions in rats[9] and baboons in response to exogenous oxytocin, and delays the progress of labor in rats.[9] We report here the ability of the oxytocin antagonist to inhibit spontaneous uterine contractions during the last trimester of pregnancy in the baboon. Our results show that the oxytocin antagonist is a potent inhibitor of nocturnal uterine contractions and contractions related to labor and suggest that oxytocin is a primary regulator of these types of uterine contractions during pregnancy. The data imply that the oxytocin antagonist has the potential of inhibiting uterine contractions of preterm labor in humans.

Material and methods

Baboons *(Papio anubis)* with timed pregnancies from the breeding colony of the Biological Resource Laboratory at the University of Illinois were used in these studies. The animals were kept under controlled lighting conditions (12 hours light/12 hours dark) with lights on at 6 AM (Central Standard Time) and fed Purina Primate Chow (Ralston Purina, St. Louis) fruit, and nuts once a day and water as desired. Normal delivery occurs at 184 ± 2 days. The protocol for this report has been approved by the Animal Care Committee at the University of Illinois.

Surgical procedures and postsurgery care. All baboons were operated on between 125 and 135 days of pregnancy. Before operation, ultrasonography was performed on all animals to determine fetal viability, as well as the location of the placenta and pockets of amniotic fluid for inserting the cannulas. Animals were initially sedated with an intramuscular injection of ketamine (7 mg/kg) and an intravenous injection of Surital (Parke Davis, Division of Warner-Lambert Co., Morris Plains, N.J.) (2 ml intravenously of a 2.5% solution). Anesthesia was maintained with 0.8% to 1.0% halothane (Wyeth-Ayerst, Philadelphia) during the operation. A midline incision was made just above and

lateral to the umbilicus. Two 0.86 × 1.32 mm vinyl cannulas (Bolabs Inc., Lake Havasu City, Ariz.) were inserted within 4 cm of each other directly through the uterine wall into the amniotic fluid via a 16-gauge needle acting as a trocar. Location of the cannula insertion was determined by the previous ultrasonogram. Approximately 15 inches of cannula was threaded into the amniotic fluid. The cannulas were then anchored to the serosal layer of the uterus with a 3-0 silk suture. The cannulas were exteriorized via a midlateral flank incision with a subcutaneous tunneling needle (Alice King Chatham Medical Art, Los Angeles). The midventral incision was closed with Vicryl suture. An incision was made in the groin area of the leg just above the external femoral vessels and artery. The vein and artery were dissected free and 0.86 × 1.32 mm vinyl tubing was placed into incisions in the vein and artery. A sufficient length of tubing (approximately 10 inches) was placed into the vein so that the tip rested in the vena cava or aorta just above the bifurcation, as determined by the location of the abdominal umbilicus. The cannulas were anchored with 3-0 silk suture and were exited subcutaneously at the junction of the leg and abdomen with tunneling needles. The leg incision was closed with 2-0 Vicryl (Ethicon, a subsidiary of Johnson and Johnson, Somerville, N.J.) suture. The four cannulas (two amniotic fluid, one femoral artery, and one femoral vein) were led subcutaneously to a middorsal, area just inferior to the scapula. The skin incisons for tunneling were then closed with 2-0 Vicryl. A nylon mesh jacket (Alice King Chatham Medical Art) was placed on the baboon, and the cannulas were led out through a flexible stainless steel tether attached to the back of the jacket. The length of the tether was 24 inches. The tether was attached to a swivel on the side of the cage; this training swivel had been punched out in the middle. This technique allowed the cannulas to be led directly out of the cage and attached to pressure transducers or infusion pumps.[3] The amniotic fluid cannulas were attached to Gould model P23id pressure transducers and pressure changes were recorded on a four-channel, model 7 Grass polygraph (Grass Instruments, Quincy, Mass.). In addition, the analog signal of the intrauterine pressure changes was digitized with a Data Translation 2811 H board on a Dell PC Limited 286 computer, and these data were stored on a hard disk. This signal was sampled every second.

The cannulas in the femoral vein and artery were attached to syringes on a Harvard infusion pump (Harvard Apparatus Co., Millis, Mass.). Heparin (100 U/ml) and Kefzol antibiotic (Eli Lilly & Co., Indianapolis), 71.4 mg/ml in saline solution, were infused at a rate of 0.582 ml/hr to keep the cannulas patent and deliver 1 gm of Kefzol antibiotic per day to the animals. After the first week the Kefzol was reduced to 0.5 gm/day. We have had few maternal infections using this method.

Oxytocin antagonist. The solid phase synthesis of the oxytocin antagonist [β-mercapto-β,β-cyclopentamethylene propionic acid-D-Trp^2-Phe^3-Ile^4-Arg^8]-oxytocin has been previously described.[10]

Uterine contractility studies. Uterine contractions were monitored 24 hours a day through delivery. The oxytocin antagonist was tested on three types of uterine contractions: (1) immediately after operation, (2) during nocturnal activity, and (3) near (≤3 days) or at labor. The oxytocin antagonist was given as an intravenous bolus injection in the range of 500 to 3000 nmol, except in preliminary studies where the oxytocin antagonist was infused for various lengths of time (e.g., Fig. 1). The uterine contractile activity was examined 1 hour before and after the oxytocin antagonist was administered for mean amplitude, frequency, contractile force (mean amplitude × frequency), and percent contractile force per 15-minute interval. The percent contractile force was determined by dividing all values by the mean of the pre–oxytocin antagonist administration values. We examined the effect of the oxytocin antagonist on uterine activity of seven animals immediately after operation and compared it with uterine activity in six controls. Operation was usually completed by 2 to 3 PM, and the oxytocin antagonist was given between 6 and 8 PM that same evening. The measurements for the controls were performed at the same time of evening as the oxytocin antagonist–treated animals. Studies examining nocturnal uterine contractions involved 10 animals. The controls chosen for the nocturnal uterine contractions were those contractions that occurred within ±2 days of those in the treated animals at the same time of evening. Since uterine activity was not always detectable with these criteria, there were fewer control (N = 19) than treated (N = 47) studies.

Animals having labor-like contractions were defined as having a contractile force >120 per 15-minute interval occurring within 3 days of delivery. The contractile force of controls for animals in labor was determined from uterine activity occurring within 2 hours of delivery, but before abdominal pushing occurred, and meeting the criteria of a contractile force of 120 per 15-minute interval for labor-like contractions. There were four oxytocin antagonist–treated and five control animals in this study.

Statistical analysis. The data were analyzed by grouping variables (Treatment – Control vs oxytocin antagonist treated) with within-repeat-measures (Time)

analysis of variance, and when significant, differences between means were detected by Tukey's test.[11]

Results

The effect of infusing the oxytocin antagonist into a pregnant baboon showing significant uterine contractile activity is shown in Fig. 1. The uterine activity is expressed as contractile force (mean amplitude × freuqency per ½-hour intervals) during the days illustrated. As determined from preliminary studies, uterine activity was considered significant and labor-like when the contractile force was >240 per 30 minutes (e.g., 12 contractions × 20 mm Hg = 240). When the oxytocin antagonist was administered on day 154 as an intravenous bolus injection of 3000 nmol followed by infusion at 16 nmol/min for 1½ days, uterine activity was immediately suppressed and remained at baseline for the period of the infusion (Fig. 1, *A*). Ten days later (day 164) uterine activity again increased significantly, but this time the oxytocin antagonist was infused for 2 hours and induced a precipitate decrease in uterine contractions. The following day (day 165) uterine activity again increased, and the oxytocin antagonist was infused for 1 hour, resulting in immediate suppression of uterine activity (Fig. 1, *B*). Fig. 1, *C*, shows the contractile force when the animal was allowed to deliver. This, plus other data, suggested that the oxytocin antagonist did not have to be continuously infused to be effective but rather that a bolus injection might suffice. Thus for all subsequent studies a bolus injection of oxytocin antagonist was given.

Fig. 2 illustrates a computer-generated, digitized, analog signal of uterine activity in a baboon showing strong uterine activity and about to deliver. At day 176 of pregnancy (Fig. 2) 3000 nmol of oxytocin antagonist was given as an intravenous bolus injection. Contractile activity was immediately suppressed and remained at baseline for the remainder of the evening. Because of the strength of these contractions and the uterine activity during the preceding nights, it is likely that, if not suppressed, delivery would have occurred. The next day this animal went into labor as determined by the fact that the membranes ruptured, and mucus and blood were on the cage floor and in the vaginal area. A bolus injection of 3000 nmol of oxytocin antagonist caused a precipitate drop in uterine activity, but it was not toally eliminated. To determine if the uterine contractile activity could be totally suppressed, a second bolus injection of oxytocin antagonist was given about 2½ hours after the first injection, followed 1½ hours later with a continuous infusion of oxytocin antagonist at 16 nmol/min for 3 hours. The combination of the two bolus injections of oxytocin antagonist and the infusion totally eliminated uterine activity. The computer compression of the data (Fig. 3) gives the appearance of some activity, represented as spikes on the chart, but when the data were examined at normal spacing, the

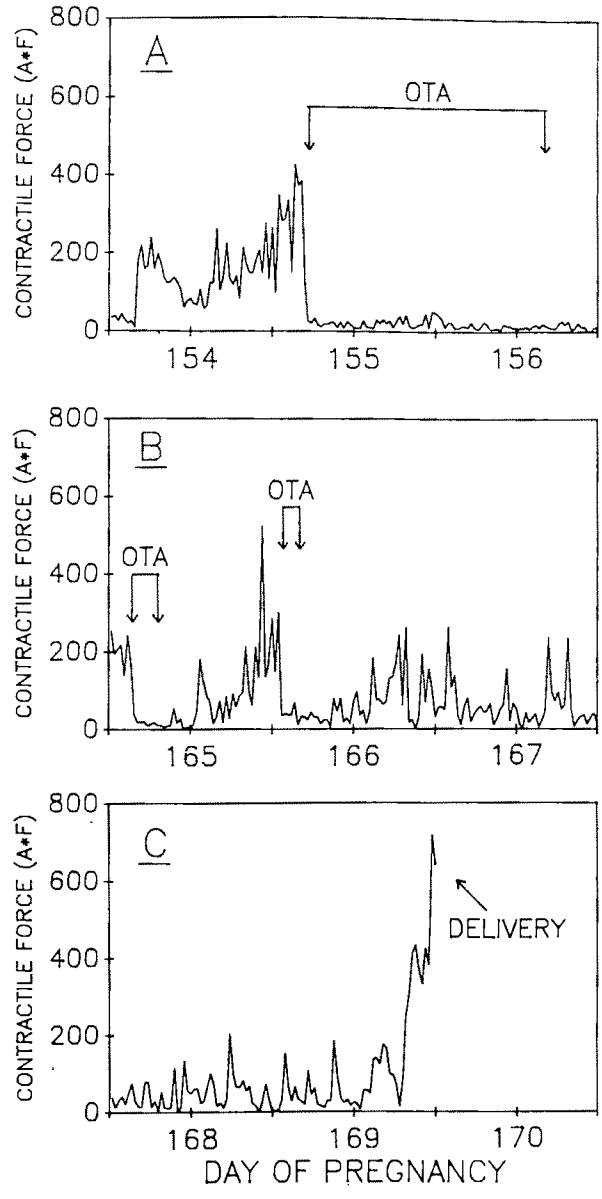

Fig. 1. This figure illustrates the effect of infusing the oxytocin antagonist *(OTA)* in an individual baboon at three different days of pregnancy when the contractile force (mean amplitude × frequency) per 30-minute interval reaches significant levels. At day 154 **(A)** the oxytocin antagonist was given initially as a bolus injection of 3000 nmol plus infused at 16 nmol/min for 1½ days. The oxytocin antagonist caused a precipitate drop in contractile force, and this force stayed at baseline during the infusion period. Similar results were noticed **(B)** when the oxytocin antagonist was infused for 2 hours (day 164) and 1 hour (day 165). **C** shows the changes in contractile force that occurred when the animal was allowed to deliver.

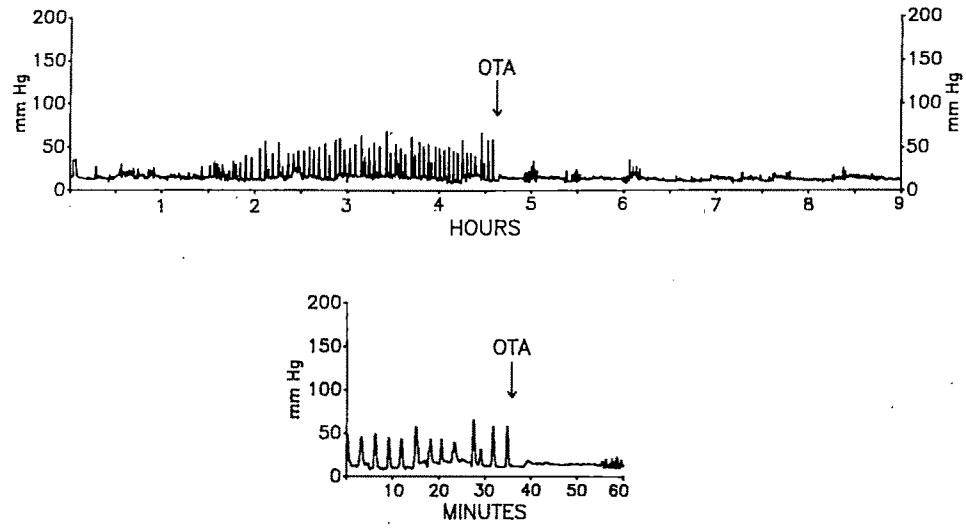

Fig. 2. Illustrated in the *top chart* is the computer-generated, digitized signal of uterine activity in a baboon showing strong nocturnal activity. As soon as an intravenous bolus injection of 3000 nmol of the oxytocin antagonist was given, contractile activity diminished and stayed at baseline the remainder of the evening. *Bottom,* An expanded view of uterine activity at the time the oxytocin antagonist was administered.

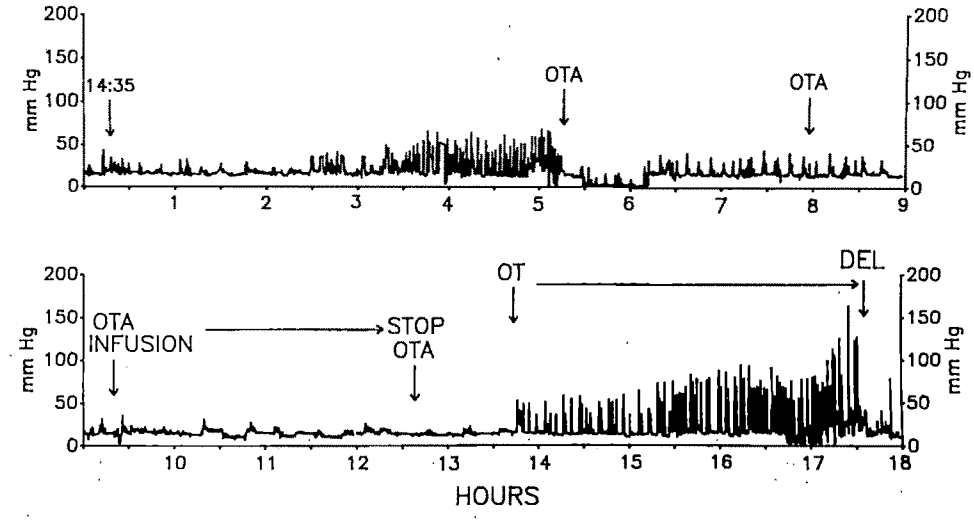

Fig. 3. Depicted in this figure is the same baboon as in Fig. 2 except labor had begun. We assumed delivery was imminent because the membranes had ruptured, mucus and blood were on the cage floor and in the vaginal area, and she was showing abdominal pushing. Bolus injections of the oxytocin antagonist (3000 nmol) caused a precipitate drop in uterine activity, but it was not totally eliminated. However, when the oxytocin antagonist was infused at 16 nmol/min, uterine contractile activity was totally suppressed. One hour after the oxytocin antagonist infusion was stopped, oxytocin *(OT)* was infused and induced immediate contractile activity that led to delivery of a live fetus in about 3½ hours.

baseline was essentially flat. After oxytocin antagonist was stopped 1 hour, the animal showed no uterine activity. To determine if the uterus would respond to exogenous oxytocin after oxytocin antagonist was stopped, oxytocin was infused starting at 10 nmol/min (5 mU/min) and stepwise increased to 50 nmol/min. Uterine contractions started immediately on oxytocin infusion; a live fetus was delivered 3½ hours later.

Figs. 4 and 5 depict the summary of all data related to nocturnal uterine activity examined within ± 1 hour at 15-minute intervals before or after oxytocin antagonist administration and expressed as amplitude, frequency, contractile force, and percent contractile force. Amplitude, frequency (Fig. 4, *A* and *B*), and contractile force (Fig. 5, *A*) showed significant decreases ($p < 0.05$) within the first 15-minute interval after the oxytocin

antagonist administration, with contractile force reflecting the most dramatic change. The control values before oxytocin antagonist (−60, −45, −30, and −15 minutes) were significantly ($p < 0.05$) less than the corresponding oxytocin antagonist group, reflecting the rationale for administering the oxytocin antagonist, which was to suppress significant uterine contractions that might lead to preterm labor. When expressed as a percentage of the baseline, the contractile force was inhibited by 70% ($p < 0.05$) within 15 minutes, and this force diminished to 90% after 1 hour (Fig. 5, *B*). The control group did not show a significant ($p > 0.05$) decrease in uterine activity over the same time intervals. The mean dose of oxytocin antagonist ± SE for 47 intravenous bolus injections was 1921.3 ± 137.5 nmol with a range of 500 to 3000 nmol. Of the 47 injections of oxytocin antagonist administered, 40 (i.e., 85%) resulted in significant suppression of uterine activity for the remainder of the evening.

When animals were near or at labor, the mean contractile force ± SEM for the oxytocin antagonist–treated group at −60, −45, −30, −15, +15, +30, +45, and +60 minutes was: 151.0 ± 20.6, 162.0 ± 26.7, 127.6 ± 15.5, 152.3 ± 33.1, 25.1 ± 7.6, 14.0 ± 5.2, 13.3 ± 3.8, and 11.4 ± 4.2, respectively. Similarly, the control values were: 209.0 ± 54.1, 130.0 ± 36.2, 164.0 ± 28.3, 138.0 ± 29.2, 128.5 ± 20.3, 187.5 ± 32.1, 160.0 ± 28.5, and 243.0 ± 34.9, respectively. The mean dose of oxytocin antagonist administered ± SEM for 10 intravenous bolus injections was 2500.0 ± 223.6 nmol with a range of 1000 to 3000 nmol. Animals received the oxytocin antagonist during the last 2 to 3 days before and/or during delivery. These results are summarized as percent contractile force in Fig.6. As with nocturnal activity, the oxytocin antagonist caused an immediate suppression of the percent contractile force ($p < 0.05$). In addition, one of the animals also received the oxytocin antagonist during the second stage of labor (defined as abdominal pushing in the intrauterine pressure recordings) and the uterine activity was immediately suppressed.

The mean contractile force ± SEM for animals immediately after operation for 60 minutes before or after the oxytocin antagonist administration at the same time interval listed above for nocturnal activity was: 143.3 ± 22.0, 126.7 ± 29.1, 119.0 ± 24.9, 145.8 ± 28.8, 55.4 ± 10.3, 40.5 ± 6.7, 39.2 ± 10.8, and 54.3 ± 10.0, respectively. Similarly, the results for the controls were: 73.0 ± 10.3, 60.1 ± 11.3, 72.6 ± 21.9, 55.0 ± 14.6, 36.1 ± 8.9, 62.0 ± 15.3, 55.5 ± 13.7, and 49.5 ± 8.9, respectively. When uterine activity was expressed as percent contractile force and compared with nocturnal and labor contractions (Fig. 6), the oxytocin antagonist caused a significant decrease ($p < 0.05$) related to operation, but activity was usually not suppressed to baseline as often occurred with nocturnal and labor

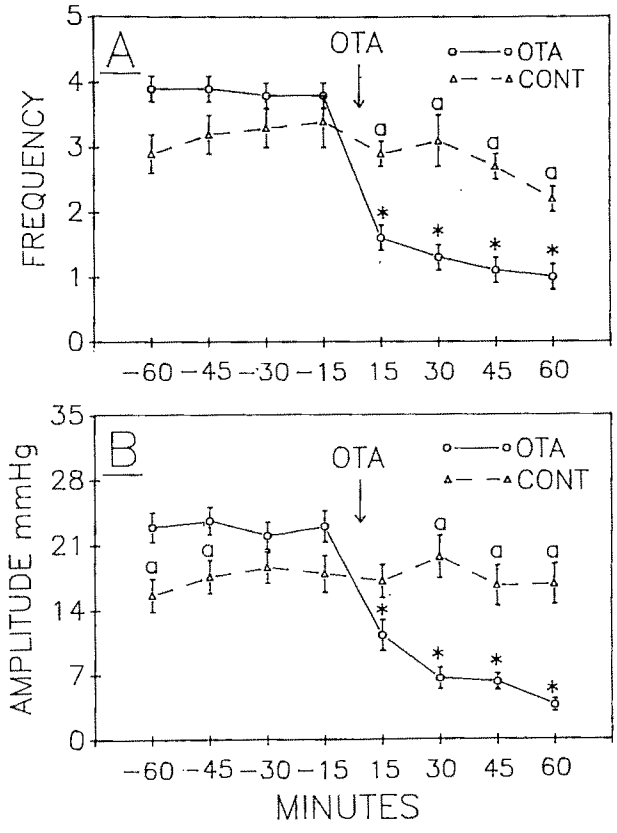

Fig. 4. This figure summarizes the effects of the oxytocin antagonist on the frequency **(A)** and amplitude **(B)** of nocturnal uterine activity 60 minutes before or after an intravenous bolus injection of the oxytocin antagonist was administered. The oxytocin antagonist caused a decrease (*asterisk*, $p < 0.05$) in frequency and amplitude within the first 15 minutes after injection of the oxytocin antagonist when compared with preinjection levels. No significant changes ($p > 0.05$) were seen for the controls when compared with their own baseline. However, when control and treated values were compared, differences were detected (*a*, $p < 0.05$). $N = 47$ and $N = 19$ for oxytocin antagonist and controls, respectively. *OTA*, Oxytocin antagonist. *CONT*, Controls. Values are mean ± SEM.

contractions. At the end of 60 minutes the percent contractile force was about 40% of baseline compared with 10% for nocturnal and labor contractions, and this was significantly different ($p < 0.05$). The mean dose of oxytocin antagonist administered ± SEM was 2416.7 ± 271.3 nmol for six intravenous bolus injections with a range of 1500 to 3000 nmol.

Comment

The results of this study show that an oxytocin antagonist is an effective inhibitor of spontaneous uterine contractions related to nocturnal activity and labor in the baboon. These data have several important implications. First, they suggest that oxytocin is a primary regulator of uterine activity during pregnancy. This does not mean that other factors (e.g., estradiol and

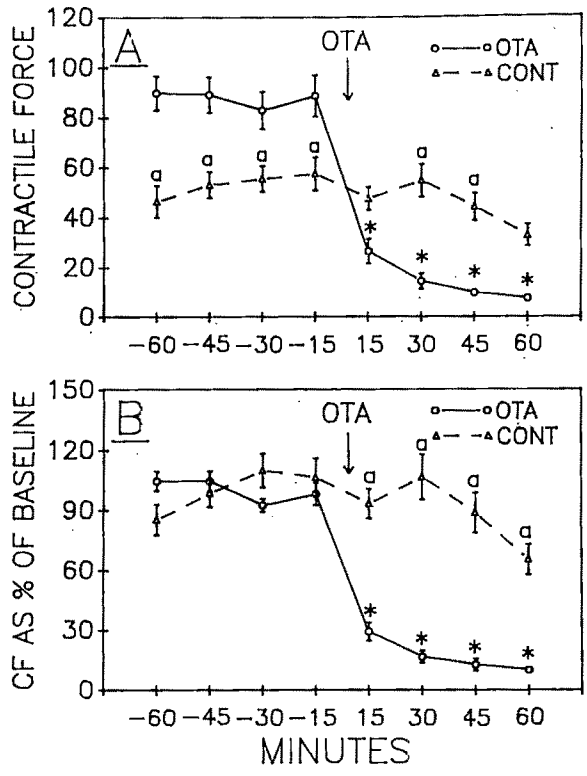

Fig. 5. The same nocturnal uterine activity data shown in Fig. 4 are shown, but they are expressed as contractile force **(A)** and percent contractile force **(B)**. A bolus injection of the oxytocin antagonist caused a precipitate drop (*asterisk*, $p < 0.05$) in uterine activity of about 70% within 15 minutes, and this activity diminished further to 90% inhibition within 60 minutes after the oxytocin antagonist injection when compared with baseline. No differences ($p > 0.05$) were found in controls when compared with baseline values, but differences were detected (*a*, $p < 0.05$) when compared with treated animals. The percent contractile force in **B** was determined by averaging the preinjection oxytocin antagonist data and dividing all values by this mean. *OTA*, Oxytocin antagonist. *CONT*, Controls. Values are mean ± SEM. Contractile force = (mean amplitude × frequency)/15 minutes. $N = 47$ and $N = 19$ for oxytocin antagonist and controls, respectively.

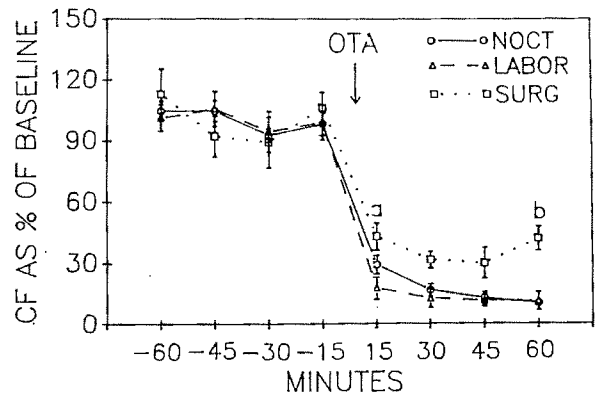

Fig. 6. This figure compares the contractile forces as a percent of baseline (see Fig. 5 for explanation) for nocturnal, labor, and surgery-related uterine activity. Uterine activity was diminished significantly (*asterisk*, $p < 0.05$) within 15 minutes for all study groups when compared with baseline. However, percent contractile force in the surgery group was decreased only by 60% 60 minutes after the intravenous bolus injection of the oxytocin antagonist, and this was statistically different (*b*, $p < 0.05$) from the nocturnal and labor activity, which was diminished by 90%. *OTA*, Oxytocin antagonist. *NOCT*, Nocturnal. *SURG*, Surgery. $N = 47$, $N = 10$, and $N = 7$ for nocturnal, labor, and surgery, respectively. Values are mean ± SEM. *a*, Different from the labor group ($p < 0.05$) but not the nocturnal group ($p > 0.05$).

prostaglandins) are not important for creating the appropriate environment or mediating oxytocin action but that oxytocin is directly responsible for controlling this uterine activity. The uterine activity may be a consequence of the change in uterine sensitivity to oxytocin, an increased release of oxytocin, or both. Such changes have been shown to occur with 24-hour rhythms in the rhesus monkey[12, 13] and baboon.[14] Also, the studies with the rhesus monkey[13] have shown that an oxytocin antagonist, different from the one in the present study, inhibits nocturnal uterine activity in this species. The fact that the oxytocin antagonist in the present study inhibits not only nocturnal uterine activity but also activity related to labor supports the concept that oxytocin is also an important regulator of this type of uterine activity. This is an important concept since the literature on humans has been ambiguous as to the stage of pregnancy or labor (first or second) in which oxytocin plays a role.[5-8] Assuming that the baboon is an appropriate model for human pregnancy, these data indicate that oxytocin is probably an important regulator of spontaneous nocturnal and labor uterine contractions in humans. These results support the studies showing that ethanol inhibits labor by suppressing oxytocin release.[15, 16]

Second, because of the physiologic similarity between baboons and humans, it seems likely that the oxytocin antagonist will inhibit spontaneous uterine actvity in humans. This assumption is supported by reports in the literature that a structurally different oxytocin antagonist can inhibit uterine activity of preterm labor in humans.[17] Thus our own data plus those in the literature imply that our oxytocin antagonist has the potential of inhibiting preterm labor in humans.

The fact that the oxytocin antagonist was not as effective in suppressing uterine contractile activity immediately after the operation when compared with spontaneous nocturnal and labor uterine contractions was not unexpected. It is likely that trauma to the uterus related to operation releases factors, such as prostaglandins, and these generate the uterine contractions. Under these conditions the generator for uterine contractions is local. However, since oxytocin release can

be induced reflexively (the Ferguson reflex[18]) by uterine contractions, one might expect oxytocin to be released and to contribute to this uterine activity. This is supported by the observation that the oxytocin antagonist appears to suppress uterine activity, but not totally eliminate it, when given immediately after operation. This is in contrast to the effect of the oxytocin antagonist on nocturnal uterine contractions and activity related to labor that is usually totally suppressed.

In our studies with the rat[9] the oxytocin antagonist disrupts labor, mainly by delaying its progress, but it does not appear to be as effective in inhibiting spontaneous uterine contractions as it is in the primate. Thus the oxytocin antagonist appears to be more efficacious in the primate than in the rat. In addition, the rat often showed incidences of diuresis (polydypsia and polyuria) while the baboons showed no apparent evidence of this potential side effect. Although this side effect is of concern, clinically it can be compensated by increasing water uptake. The opposite effect, antidiuresis, would be of greater concern.

The observation in Fig. 3 that oxytocin could reinitiate labor within 1 hour after oxytocin antagonist administration is important; if the oxytocin antagonist is used clinically, there would be occasions when labor needs to be reinitiated after the patient is evaluated. This observation suggests that within 1 hour, and perhaps less, the uterus will respond to exogenous oxytocin. Although not shown, the uterus will respond to exogenous prostaglandin $F_{2\alpha}$ and E_2 in the presence of oxytocin antagonist. Thus this is another potential means of reinitiating labor after oxytocin antagonist administration.

We have observed that the mother can express milk and the newborns can suckle within hours after delivery even though the oxytocin antagonist was given to the mother the day of or just before delivery. Therefore, even though the oxytocin antagonist can inhibit milk let-down,[9] this effect appears to be short-lived and should not interfere with nursing within several hours after delivery. However, this may not be the situation if the oxytocin antagonist is infused for long periods of time rather than given as intravenous bolus injections as in the present study.

Finally, it should be emphasized that the oxytocin antagonist has both antioxytocin and anti-antidiuretic hormone activity. Thus, although it seems likely that the oxytocin antagonist inhibits uterine activity by blocking endogenous oxytocin, it may be acting by blocking antidiuretic hormone as well. There are reports in the literature suggesting a role for antidiuretic hormone in labor.[19] Further studies are needed to assess this possibility.

In summary, we have shown that an oxytocin antagonist is a potent inhibitor of nocturnal uterine contraction and contraction related to labor in the baboon. These data suggest that oxytocin is the primary regulator of spontaneous nocturnal and labor uterine contraction during pregnancy in the baboon. Because of the physiologic similarity between humans and baboons the data imply that oxytocin is probably a primary regulator of uterine contractions in humans, and thus the oxytocin antagonist has the potential of inhibiting uterine contractions of preterm labor in humans.

We are indebted to Drs. Peter Nathanielsz, Department of Physiology, College of Veterinary Medicine, Cornell University, Ithaca, N.Y., and Raymond Stark, Department of Pediatrics, College of Physicians and Surgeons of Columbia University, New York, for allowing us to visit their laboratories and observe and discuss techniques required for establishing the tethered baboon model. In addition, we would like to thank Drs. Scott Walsh, Department of Obstetrics and Gynecology, Medical School of Virginia, Richmond, and George Haluska, Oregon Regional Primate Research Center, Portland, for additional advice in developing this model.

We thank Joanne McNeal and Denise Almahdi for helping with the baboon surgery and Irma Lopez for assistance in the manuscript preparation. Also we acknowledge the Scientific Computer Workstation and the Biostatistics Facility of the Research Resources Center, University of Illinois at Chicago, which provided the equipment and assistance necessary to conduct these computations.

Evidence of a role for protein kinase C in epidermal growth factor–induced prostaglandin E_2 synthesis in amnion cells

Human amnion cells synthesize and release prostaglandin E_2 in response to epidermal growth factor. The protein kinase C activator, phorbol 12-myristate, 13-acetate also stimulates amnion cell prostaglandin E_2 synthesis. We used a human amnion cell line (WISH) to conduct in vitro experiments to investigate a potential role of protein kinase C in the signal transduction pathway leading to epidermal growth factor–induced prostaglandin E_2 production. Pretreatment of cultured amnion cells with a low, nonstimulating dose of phorbol 12-myristate, 13-acetate potentiated the action of epidermal growth factor in causing prostaglandin E_2 production as measured by radioimmunoassay. The protein kinase C–selective inhibitor staurosporine inhibited epidermal growth factor–induced prostaglandin E_2 production, further suggesting a role for protein kinase C in epidermal growth factor action. Experiments were conducted in which amnion cells were rendered protein kinase C–deficient by chronic exposure to phorbol ester, which has been shown to down-regulate the enzyme. In these cells, epidermal growth factor caused prostaglandin E_2 synthesis at levels comparable to native (non-protein kinase C–deficient) cells. We conclude that protein kinase C plays a more modulatory than direct role in the epidermal growth factor signal transduction cascade that leads to prostaglandin E_2 production by amnion cells. We propose a bifurcating transduction scheme in which, under conditions of protein kinase C inactivation, epidermal growth factor alone causes prostaglandin E_2 synthesis. When protein kinase C is activated by as yet unknown endogenous substances, the epidermal growth factor responsiveness of the amnion cells is greatly enhanced. This pathway could have important implications in a feed-forward mechanism regulating the level of prostaglandin E_2 production during the onset of labor. (Am J Obstet Gynecol 1990;163: 1883-90.)

Key words: Amnion cells, cell culture, prostaglandin E_2, EGF, protein kinase C

It is now well established that prostaglandins E_2 (PGE_2) and $F_{2\alpha}$ ($PGF_{2\alpha}$) are the active mediators of two key parturitional events, cervical ripening and myometrial contractions. Arachidonic acid and prostaglandins accumulate in amniotic fluid in association with the onset of labor at term.[1] In addition, Romero et al.[2] have reported the presence of high levels of PGE_2 and $PGF_{2\alpha}$ in amniotic fluid samples obtained from women in preterm labor complicated by intraamniotic infection. The human amnion membrane is thought to be a major contributor to the amniotic fluid pool of PGE_2, and as such, the fetal membranes may play an important role in the onset of labor.[3, 4] However, it is not yet clear which signal molecules govern amnion prostaglandin production. One candidate molecule is epidermal growth factor. Because epidermal growth factor levels in human amniotic fluid increase steadily from 30 to 40 weeks' gestation and epidermal growth factor stimulates the production of PGE_2 in primary cultures of human amnion cells, investigators proposed that this molecule plays an important role in perinatal development and parturition.[5-7] Moreover, epidermal growth factor has been suggested to be derived, at least in part, from the fetal kidney, thus supporting the hypothesis that the signal triggering labor in women emanates from the fetus.[5, 8, 9] Epidermal growth factor is thus an attractive molecule for further studies of the regulation of amnion cell prostaglandin production.

There is evidence that activation of protein kinase C by tumor-promoting phorbol esters causes PGE_2 synthesis in amnion cells, and calcium-sensitive/phospholipid-dependent protein kinase activity has been characterized in amnion tissue.[10-12] Because epidermal growth factor in other cell systems acts at least partially via a protein kinase C–mediated mechanism, we sought to determine whether protein kinase

C activation was involved in epidermal growth factor–induced PGE_2 synthesis in human amnion cells.[13-16] For our studies, we used the established human amnion cell line (WISH) as a model system.[17] Harris et al.[18] have reported that WISH cells respond to phorbol esters and epidermal growth factor by producing PGE_2, as do primary cultures of human amnion cells.

WISH cells have the added advantages of being more stable and providing a more homogeneous population of cells than primary amnion cell cultures. Our data suggest that epidermal growth factor may exert part of its PGE_2 synthesizing action via a protein kinase C–associated pathway.

Material and methods

Cell cultures. The established human amnion cell line (WISH) obtained from the American Type Culture Collection (ATCC, CCL25) was maintained in Ham's F12/Dulbecco's modified Eagle's medium (1:1) supplemented with 2 mmol/L L-glutamine, 1 mmol/L sodium pyruvate, 50 μg/ml gentamicin sulfate, and 10% newborn calf serum. The cells were subcultured once weekly, and, when used for experiments, were seeded into NUNC 24-well plates (2×10^5 cells per well) or Corning 12-well plates (5×10^5 cells per well). After 2 days' growth, the cells were 80% to 90% confluent; they were then rinsed with serum-free F12/Dulbecco's modified Eagle's medium and treated with test substances. The cells were stimulated for 4 to 12 hours. The incubation media were collected and analyzed for the presence of PGE_2 by specific radioimmunoassay (RIA).

PGE_2-specific radioimmunoassay. Media collected from stimulated WISH cell cultures were analyzed for the presence of PGE_2 by specific RIA with anti-PGE_2 prepared by inoculating domestic chickens with PGE_2-keyhole limpet hemocyanin conjugate. The full protocol for the preparation of this antibody has been published elsewhere.[19] The percent cross-reactivity for this antibody is as follows: arachidonic acid, 0.01%; PGA, 0.16%; PGD_2, 1.6%; PGE_2, 100%; $PGF_{1\alpha}$, 3.2%; $PGF_{2\alpha}$, 0.75%; 6-keto-$PGF_{1\alpha}$, 0.05%; thromboxane B_2, 0.41%.

Tritiated phorbol 12,13-dibutyrate binding studies. WISH cells were seeded into Costar 12-well plates at 2.5×10^5 cells per well in F12/Dulbecco's modified Eagle's medium + 10% newborn calf serum. One day after plating the cells were exposed to 1 μmol/L phorbol 12,13-dibutyrate or 0.001% dimethyl sulfoxide in the same media for 48 hours. After exposure to phorbol 12,13-dibutyrate, the cells were rinsed five times with warm Ham's F10 supplemented with 15 mmol/L Hepes (pH 7.2) and 1 mg/ml bovine serum albumin. The cells were then exposed to tritiated phorbol 12,13-dibutyrate (1 to 50 nmol/L) for 60 min at 37° C. Nonspecific binding was assessed by treating companion wells with 1 μmol/L phorbol 12-myristate, 13-acetate during the binding interval and subtracting the amount of ligand bound in the presence of phorbol 12-myristate, 13-acetate from total binding. After the binding period the cells were rinsed extensively with F10 medium and then solubilized with 1% Triton X-100/1% sodium dodecyl sulfate. Radioactivity was counted by liquid scintillation spectrometry.

Protein kinase C down-regulation studies. To down-regulate protein kinase C in the WISH cells, they were treated 1 day after seeding with 1 μmol/L phorbol 12,13-dibutyrate or 0.001% dimethyl sulfoxide as described. Two days after phorbol treatment the cells were rinsed extensively to remove the phorbol 12,13-dibutyrate and were then treated with epidermal growth factor, phorbol 12-myristate, 13-acetate, or vehicle. Preliminary experiments with tritiated phorbol 12,13-dibutyrate as a tracer demonstrated that with extensive rinsing 95% of the phorbol 12,13-dibutyrate could be removed from the cells.

Statistical analysis. Each experiment was performed with six replicates per condition. In all cases the experiments were repeated a minimum of two times. The data were analyzed with Student's t test (two-tailed) to determine statistically significant differences between control and treatment groups.

Material. All tissue culture reagents were obtained from Gibco/BRL (Grand Island, N.Y.). Phorbol esters and dimethyl sulfoxide were purchased from Sigma Chemical Co. (St. Louis). Murine epidermal growth factor was from Collaborative Research (Bedford, Mass.). Staurosporine was obtained from Boehringer Mannheim (Indianapolis). Tritiated PGE_2 was purchased from Amersham (Arlington Heights, Ill.).

Results

Effect of phorbol esters on PGE_2 synthesis in amnion cells. To determine whether protein kinase C is associated with PGE_2 production in WISH cells, we incubated cells with phorbol 12-myristate 13-acetate, phorbol 12,13-dibutyrate, or 4α-phorbol at concentrations ranging from 10^{-7} to 10^{-10} mol/L. Our results (Fig. 1) indicate that, at a concentration of 10^{-7} mol/L, phorbol 12-myristate, 13-acetate caused an eighteenfold increase in PGE_2 production versus control ($p < 0.001$). Phorbol 12,13-dibutyrate, a less potent analog of phorbol 12-myristate, 13-acetate, caused a tenfold increase in PGE_2 production ($p < 0.01$). In contrast, the inactive phorbol, 4α-phorbol, had no effect on PGE_2 production. On the basis of this experiment, we concluded that active phorbol esters stimulate PGE_2 production in WISH cells.

Synergistic effect of epidermal growth factor and phorbol 12-myristate, 13-acetate on PGE_2 synthesis. To determine whether epidermal growth factor and phorbol 12-myristate, 13-acetate act via a similar mech-

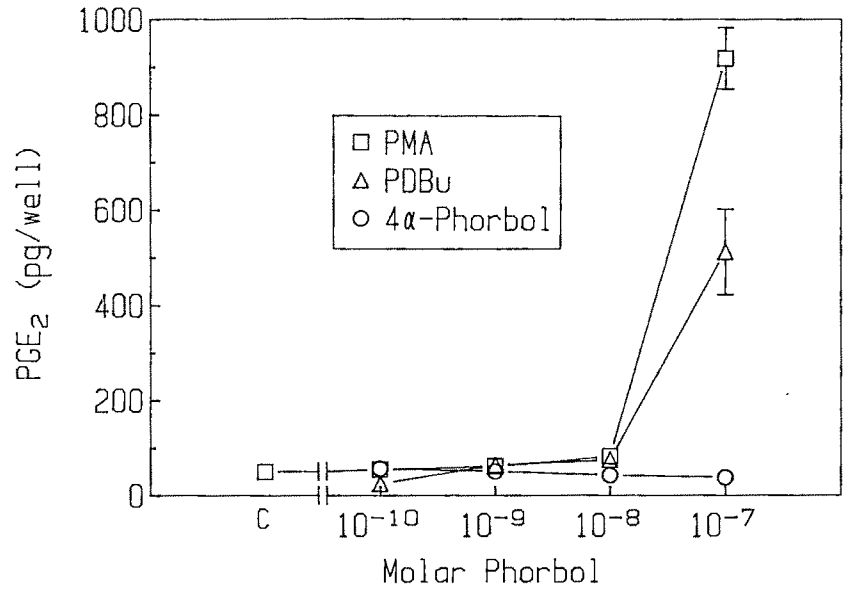

Fig. 1. Phorbol dose-response. WISH cells were seeded into 24-well plates at 2×10^5 cells/well and grown for 2 days. The cells were then treated with either phorbol 12-myristate, 13-acetate, phorbol 12,13-dibutyrate, or 4α-phorbol at concentrations ranging from 10^{-7} to 10^{-10} mol/L in F12/Dulbecco's modified Eagle's medium plus 10% newborn calf serum. Control cultures were incubated with 0.01% dimethyl sulfoxide. After 12 hours of stimulation, the media were collected and analyzed for the presence of PGE_2 by radioimmunoassay. The data, expressed as picograms of PGE_2 produced per well per 12 hours, represent the mean ± SEM of six replicates per condition and are representative of two individual experiments. Student's *t* test revealed significant differences between 10^{-7} mol/L phorbol 12-myristate, 13-acetate and control and 10^{-7} mol/L phorbol 12,13-dibutyrate and control, $p < 0.001$. All other phorbol concentrations were not significantly different from controls ($p > 0.05$). (*C*, Control; *squares*, phorbol 12-myristate, 13-acetate; *triangles*, phorbol 12,13-dibutyrate; *circles*, 4α-phorbol.)

anism, we studied the effect of a stimulatory concentration of epidermal growth factor (10 ng/ml) on amnion cell PGE_2 synthesis in the presence or absence of a substimulatory dose of phorbol 12-myristate, 13-acetate (1 nmol/L). Our results (Fig. 2) indicate that 10 ng/ml of epidermal growth factor caused a tenfold increase in PGE_2 production by the WISH cells after a 4-hour incubation period ($p < 0.001$). At a concentration of 1 nmol/L, phorbol 12-myristate, 13-acetate had a minimal effect on PGE_2 production. This is in accord with the previous dose-response experiments with phorbol 12-myristate, 13-acetate (Fig. 1). However, when epidermal growth factor was coincubated with 1 nmol/L phorbol 12-myristate, 13-acetate, there was a fifteenfold enhancement of PGE_2 synthesis over control, and a 66% enhancement over epidermal growth factor alone ($p < 0.001$). These results suggest that a concentration of phorbol 12-myristate, 13-acetate that itself is not stimulatory is capable of enhancing the effect of epidermal growth factor. To further test this idea, we preincubated the cells with phorbol 12-myristate, 13-acetate, removed the phorbol by thorough washing of the cells, and then treated the cells with a stimulatory dose of epidermal growth factor. Our results (Fig. 3) indicate that preincubation with phorbol 12-myristate, 13-acetate alone had little effect on PGE_2 production. In contrast, the epidermal growth factor response was stimulated nearly threefold by prior exposure of the cells to phorbol 12-myristate, 13-acetate ($p < 0.001$). The inactive phorbol, 4α-phorbol, which does not activate protein kinase C, had no effect on the epidermal growth factor response (data not shown). On the basis of these studies, we conclude that pretreatment or coincubation with a low dose of phorbol 12-myristate, 13-acetate (1 nmol/L) significantly enhances the responsiveness of the amnion cells to epidermal growth factor.

Effect of protein kinase C inhibitors on epidermal growth factor–induced PGE_2 synthesis. To test further the relationship between epidermal growth factor and protein kinase C activation, WISH cell cultures were pretreated with the protein kinase C inhibitor staurosporine for 30 minutes before epidermal growth factor exposure. Preliminary experiments demonstrated that staurosporine was able to inhibit phorbol 12-myristate, 13-acetate–induced PGE_2 synthesis in a dose-dependent manner (data not shown). Our results (Fig. 4) indicate that staurosporine inhibited epidermal growth factor–induced PGE_2 production in a dose-dependent manner. A concentration of 5 nmol/L stau-

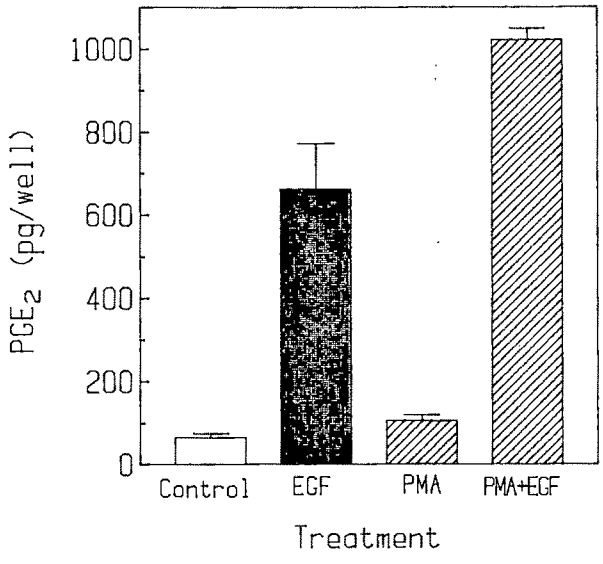

Fig. 2. Phorbol 12-myristate, 13-acetate enhancement of epidermal growth factor–induced PGE_2 synthesis. WISH cell cultures were seeded into 24-well plates at 2×10^5 cells/well and grown for 2 days. The cells were then treated with epidermal growth factor (10 ng/ml) in the presence of 1 nmol/L phorbol 12-myristate, 13-acetate. Control cultures received 0.0001% dimethyl sulfoxide. After a 4-hour incubation period, PGE_2 in the culture media was measured by radioimmunoassay. The data represent mean ± SEM of six replicates per condition and are representative of two separate experiments. ($p < 0.001$, epidermal growth factor vs phorbol 12-myristate, 13-acetate + epidermal growth factor.)

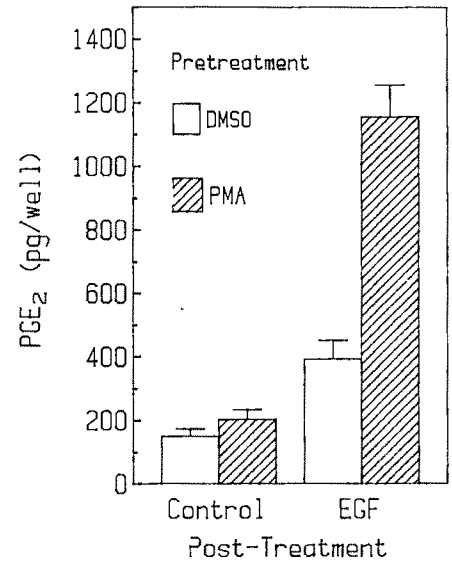

Fig. 3. Phorbol 12-myristate, 13-acetate preincubation augments the epidermal growth factor response. WISH cells were seeded into 24-well plates at 2×10^5 cells/well in F12/Dulbecco's modified Eagle's medium + 10% newborn calf serum and grown for 2 days. The cells were then fed fresh medium (serumfree F12/Dulbecco's modified Eagle's medium) containing phorbol 12-myristate, 13-acetate (0.1 μmol/L) or dimethyl sulfoxide (0.01%) for 4 hours. After the preincubation period the cells were rinsed thoroughly with serumfree F12/Dulbecco's modified Eagle's medium and then exposed to epidermal growth factor (10 ng/ml) in F12/Dulbecco's modified Eagle's medium + 10% newborn calf serum. Control cultures received medium alone. After an additional 4-hour incubation period, PGE_2 in the media was measured by radioimmunoassay. The data represent mean ± SEM of six replicates per condition and are representative of four similar experiments.

rosporine caused a 43% reduction in PGE_2 synthesis compared with epidermal growth factor alone. At 100 nmol/L staurosporine, PGE_2 synthesis in response to epidermal growth factor was reduced by 65%. Staurosporine alone had no effect on PGE_2 production (data not shown). These results provide further evidence for the role of protein kinase C in the prostaglandin synthetic pathway.

Effect of protein kinase C down-regulation on epidermal growth factor–induced PGE_2 synthesis. If protein kinase C is the only pathway by which epidermal growth factor can stimulate the production of PGE_2 in amnion cells, then down-regulation of the enzyme should diminish or abolish the epidermal growth factor response. To test this possibility, we preincubated the cells with phorbol 12,13-dibutyrate (1 μmol/L) for 48 hours to down-regulate protein kinase C. Previous studies have shown that long-term exposure to a high dose of phorbol ester is sufficient to eliminate nearly all the protein kinase C.[19, 20] To verify the down-regulation phenomenon, we used tritiated phorbol 12,13-dibutyrate to evaluate the presence of phorbol binding sites (i.e., protein kinase C) after chronic phorbol exposure. As predicted, there was an 85% reduction in phorbol binding sites in chronically phorbol-treated cells compared with vehicle-treated (dimethyl sulfoxide) controls (Fig. 5, inset). On the basis of this study, we conducted experiments to examine the effect of protein kinase C down-regulation on epidermal growth factor–induced PGE_2 synthesis. When the cells were chronically exposed to 1 μmol/L phorbol 12,13-dibutyrate and then challenged with phorbol 12-myristate, 13-acetate 48 hours later, there was a complete diminution of phorbol 12-myristate, 13-acetate–induced PGE_2 production (Fig. 5, $p > 0.01$ for dimethyl sulfoxide vs phorbol 12,13-dibutyrate pretreatment in the phorbol 12-myristate, 13-acetate–treated group). In contrast, when protein kinase C "deficient" cells were challenged with epidermal growth factor, there was no apparent reduction in PGE_2 synthesis. In fact, there was a modest, albeit statistically significant, enhancement of epidermal growth factor–induced PGE_2 production (Fig. 5, $p < 0.05$, for dimethyl sulfoxide vs phorbol 12,13-dibutyrate pretreatment in epidermal growth factor–treated group). These data suggest that, although protein kinase C is likely involved in epidermal growth factor–induced PGE_2 production by am-

nion cells, a protein kinase C–*independent* pathway may also exist.

Comment

In this study we sought to determine whether epidermal growth factor–induced PGE_2 synthesis in cultured human amnion cells was mediated via a protein kinase C–dependent pathway. For our studies we used the immortal human amnion cell line (WISH) as a model system. A previous report by Harris et al.[18] provided evidence that WISH cells respond to phorbol esters and epidermal growth factor by producing eicosanoids (primarily PGE_2). Similar results have been reported by several laboratories using primary amnion cell cultures.[10, 12, 21, 22] In our hands, the WISH cell line has been much more stable than primary amnion cell cultures prepared from fetal membranes obtained at cesarean section. Thus we believe that the WISH cells offer another model system for studies of the mechanisms governing PGE_2 production in amnion cells.

Our studies, in which a low, nonstimulating concentration of phorbol 12-myristate, 13-acetate augmented the epidermal growth factor response, suggest that protein kinase C activation may be involved in the transduction pathway leading to epidermal growth factor–induced prostaglandin synthesis in amnion cells. A recent report by Sanders and Myatt[23] has clearly established a role for protein kinase C in the amnion cell prostaglandin cascade by showing that several putative inhibitors of protein kinase C abolished phorbol 12-myristate, 13-acetate–induced PGE_2 production. Our results are in accordance with the findings of Margolis et al.,[24] who reported that, in rat kidney glomerular mesangial cells, epidermal growth factor and phorbol esters interacted synergistically to stimulate arachidonic acid liberation and PGE_2 production. In addition, our studies showing that the inactive phorbol ester 4α-phorbol failed to synergize with epidermal growth factor provide further evidence that activation of protein kinase C by active phorbols (i.e., phorbol 12-myristate, 13-acetate) is required for potentiation of the epidermal growth factor signal. To test this concept further, we used the selective protein kinase C inhibitor staurosporine. Although staurosporine shows some inhibitory activity for cyclic adenosine monophosphate–dependent and calcium/calmodulin-dependent protein kinases, it appears to be fairly selective for protein kinase C, especially at lower concentrations (e.g., 5 to 50 nmol/L).
